Keywords

cwESR
ESR signal detected with radiation turned on continually during recording.

EPR, PMR, EMR
Synonyms, in practice, for ESR: electron paramagnetic resonance, paramagnetic resonance, and electron magnetic resonance.

EPRI
In vivo imaging based on the ESR signal of a paramagnetic molecule.

ESR
Electron Spin Resonance. Spectroscopy involving unpaired electrons in a magnetic field.

ENDOR
Electron-Nuclear Double Resonance spectroscopy. Spectroscopy in which NMR signals are observed as changes in intensity of ESR signals.

ESEEM
Electron Spin Echo Envelope Modulation spectroscopy. A pulsed ESR technique in which nuclear moments modulate time-dependent electron relaxation.

g-factor
Proportionality constant between ESR frequency applied and the magnetic field where ESR absorption occurs.

Hyperfine Splitting
An ESR signal of an unpaired electron is split into multiple signals, one for each dipolar interaction with a unique nuclear spin.

Isotropic or Anisotropic
Uniform or asymmetric, respectively, with regard to coordinates in space.

Pulsed ESR
ESR signal detected as a function of time after a pulse of energy.

Spin Label
Paramagnetic molecule used to provide information about a nonparamagnetic biomolecule with which it interacts; the same term is used in nuclear magnetic resonance imaging for manipulations of nuclei in a portion of the sample to amplify the NMR signal from localized regions.

Spin Trap
A means of capturing information from a radical that has a short lifetime or other properties rendering it unsuitable for ESR so that, when trapped, useful ESR signals result.

Electron spin resonance (ESR) refers to spectroscopy of unpaired electrons, and is sometimes called electron paramagnetic resonance (EPR) or electron magnetic resonance (EMR). The theoretical bases of ESR spectroscopy are similar to those of nuclear magnetic resonance (NMR), except that an electron spin, rather than a nuclear spin, is the focus. Unpaired electrons in biological systems are in much lower abundance than nuclei, so ESR is a technique that focuses on local sites while NMR is more global.

Two electrons are paired, with antiparallel spins, in a single chemical bond. The ESR requirement of an unpaired electron spin is met in biology when (1) a chemical bond is broken homolytically, as in formation of a free-radical enzyme intermediate; (2) there are unfilled valence orbitals, as there are in oxygen, nitric oxide, or many metal ions; and (3) one-electron oxidation or reduction of a nonparamagnetic biomolecule has occurred. Biological subjects for ESR include free-radical enzyme intermediates, metal ions, nitric oxide and some of its complexes, and redox-active cofactors such as quinones and flavins. The range of applications of ESR spectroscopy is not limited to natural sources of unpaired electrons. An ESR probe technique, site-directed spin labeling (SDSL), is widely applied to examine dynamics and folding of biomolecules. Other paramagnetic probes can be used to image oxygen or nitric oxide in biological tissues *in vitro* and *in vivo*.

1 Basic ESR Concepts and Spectra

The term "spin" in the designations of various forms of magnetic resonance spectroscopy refers to a property of electrons (or nuclei). It is the interaction of the spin with magnetic field that leads to separation of energy levels between which spectroscopic transitions occur. Usually, a magnetic field is required for ESR, as well as a source of energy to effect transitions, although a few spin transitions can be detected in the absence of an applied magnetic field.

ESR signals can be detected during continuous application of microwave energy of narrow bandwidth (continuous wave ESR, cwESR) or after a short, broader-band microwave pulse (pulsed ESR). In the former case, the signal is detected by scanning the external magnetic field through the resonance condition; in the latter, the field is fixed for each pulse, but, because of the breadth of many ESR signals, data may be collected at multiple steps in magnetic field. To filter noise, a cwESR signal is recorded with an additional magnetic field modulation and phase-sensitive detection, resulting in an output that is the derivative of the absorption. Absorption and derivative ESR signals are illustrated in Figs. 1(a, b).

Equation (1) gives the resonance condition for a free electron, where ν is the microwave frequency; g_e is Zeeman splitting constant for a free electron; β_e, the Bohr magneton, is proportional to the charge to mass ratio of the electron; and B_0 is the external magnetic field in which the sample resides.

$$\text{Energy} = h\nu = g_e \beta_e B_0 \qquad (1)$$

Internal magnetic fields in molecules alter the simple spectrum shown in Fig. 1(b)

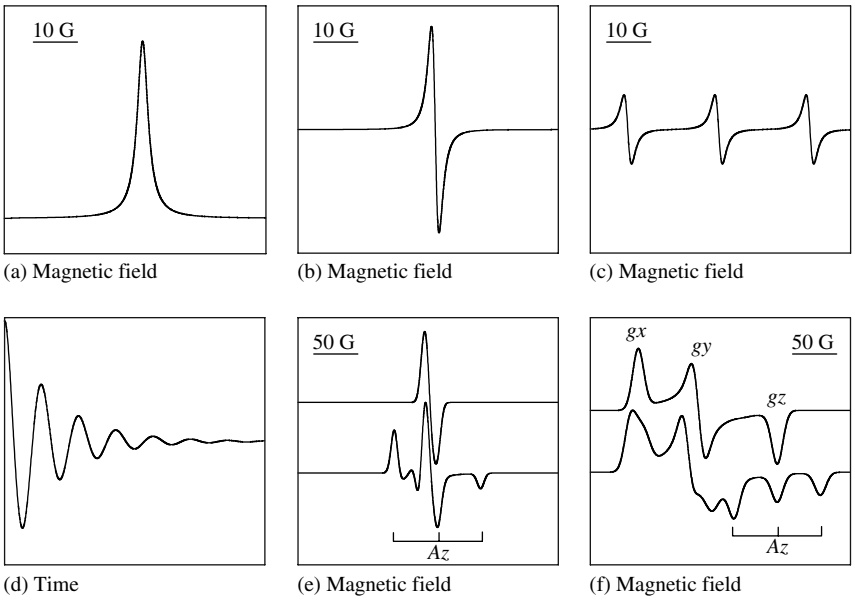

Fig. 1 Basic ESR spectra concepts are illustrated. (a) An isolated, unpaired electron has an absorption ESR signal of Lorentzian shape; (b) in cwESR, the signal shown in (a) is recorded as the derivative of the absorption; (c) when a nuclear spin interacts with the unpaired electron, the signal is split into multiple lines, one for each nuclear spin state (^{14}N spin states are -1, 0, and $+1$); (d) the time-dependent response of an unpaired electron to a pulse is an oscillating decay; (e) and (f) are spectra with parameters typical of spin labels recorded at 9.4 GHz (e) and 94 GHz (f). In (e) and (f), the upper spectra are calculated with only *g*-factor anisotropy, while the calculations of the lower spectra include anisotropic terms for both *g*-factor and hyperfine splitting. The largest hyperfine splitting, *Az*, is shown.

and thus provide the features that allow information about structure and dynamics to be deduced. The local magnetic fields add terms to Eq. (1), and it is convenient to refer to the proportionality between the frequency applied and the magnetic field at which a characteristic feature is seen in the ESR spectrum in terms of an ''effective *g*-factor,'' g', as given in Eq. (2).

$$h\nu = (g_e \beta_e B_0 + \text{other terms}) = g' \beta_e B_0 \tag{2}$$

The ''other terms'' include, but are not limited to, those of electron spin dipolar interactions with spins of nuclei or other unpaired electrons, spin exchange due to overlap of the orbitals of two electron spins, and terms arising from strong interactions of multiple electrons residing on the same atom. Different terms dominate the ESR spectrum in varied applications. Some terms are described by expressions including magnetic field and other terms are independent of magnetic field. ESR spectra obtained at several different frequencies, ν, help resolve contributions of the different terms.

Dipolar interactions of magnetic nuclei (for instance, hydrogen or nitrogen) with an unpaired electron render ESR spectra sensitive to molecular structure. An unpaired electron residing in a p- or π-orbital on ^{14}N, such as occurs in a spin label or in nitric oxide (NO), has dipolar interactions

of slightly different energies with each of the nitrogen nuclear spin states (^{14}N nuclear spins −1, 0, and +1). As a result, the simple unpaired electron ESR signal becomes a spectrum with three lines, each of one-third the intensity (Fig. 1(c)) of the single line (Fig. 1(b)). The separation of the lines is termed the *hyperfine splitting* of the electron spin by the nuclear spins. Hyperfine splitting by ^{1}H or ^{15}N yields ESR spectra divided into two lines.

The response of spins to a short pulse of energy is recorded over time in pulsed ESR. The time-dependent response may be converted to the cwESR spectrum by Fourier transformation. A Fourier transform of the absorption signal (Fig. 1(a)), which would be detected in the pulsed experiment, is shown in Fig. 1(d). The exponential decay is related to the line width and the oscillations to the offset of the absorption peak from zero magnetic field. ESR and NMR are connected in the variations of pulsed ESR that are termed electron spin echo envelope modulation (ESEEM) and electron-nuclear double resonance (ENDOR), in which electron transitions are modulated by nearby nuclei. After Fourier transformation of the time response, the characteristic frequencies of nuclear spins near the electron spin are displayed in these experiments. Determining the nature, geometric arrangement, and distance of nuclei from the unpaired electron are applications of these pulsed ESR techniques.

Figures 1(a, b) are based on a fictitious "free electron." In a molecule, an unpaired electron responds to an anisotropic (asymmetric) environment, resulting in energies for the magnetic interactions that depend on the orientation of each molecule in the magnetic field. The *g*-factor becomes a matrix (**g**) relating the vectors of magnetic field, B_0, and electron spin, S. The expression of the energy for the hyperfine interaction is S **A** I, where electron and nuclear spin vectors are S and I, respectively, and **A** is the interaction matrix. The diagonal elements of the **g**- and **A**-matrices are *gx*, *gy*, and *gz* and *Ax*, *Ay*, and *Az*, respectively. As a result of these interactions, if a frozen solution is studied, the spectrum will be the sum of spectra from molecules at all orientations, and will be broader than the free electron signal. Figures 1(e, f) illustrate the type of spectra that result from a frozen solution of nitroxide molecules. Figure 1(e) is calculated for a frequency of applied radiation (9.41 GHz) 10 times lower than that of Fig. 1(f) (94.1 GHz). The upper spectra show only the contribution from the anisotropic *g*-factor. The features corresponding to *gx*, *gy*, and *gz* can hardly be seen in Fig. 1(e) (upper curve), but they are separated as indicated in Fig. 1(f) (upper curve). This is because the *g*-factor energy term depends on magnetic field. In contrast, the hyperfine term is constant. The lower curves indicate the *Az* component of the hyperfine splitting; it is centered on *gz*. *Ax* and *Ay* are smaller and are not indicated on the figures. However, it can be seen in Fig. 1(f) (lower curve) that the *gx* and *gy* regions are broadened by the smaller *Ax* and *Ay* hyperfine splittings.

2 ESR and the Roles of Naturally Occurring Paramagnetic Biomolecules

2.1 Free-radical Enzyme Intermediates

Cofactors and amino acid side chains are known to form radical, or paramagnetic intermediates in enzymes. Ribonucleotide reductases use a pathway of electron transfers to carry out reduction of

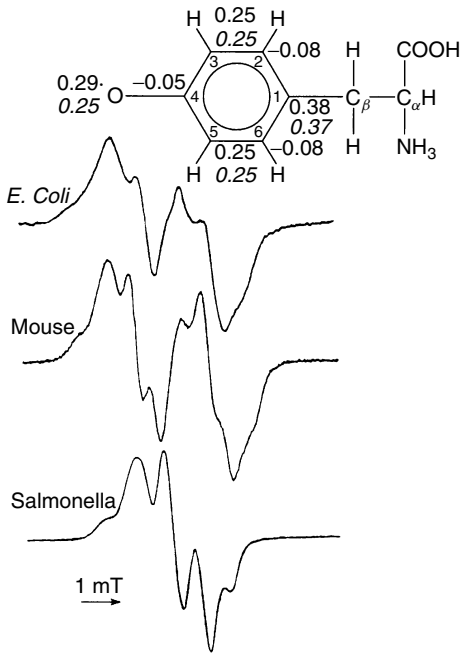

Fig. 2 ESR spectra of tyrosine free radicals of ribonucleotide reductase R2 subunits from different organisms. The ESR spectra at ~9 GHz were recorded at temperatures from 20 to 30 K. The numbers given on the structure are the spin density distributions for the *Escherichia coli* (Roman letters) and *Salmonella typhimurium* (italics) enzymes. (Reprinted with permission from Gräslund, A. and Sahlin, M. (1996) *Ann. Rev. Biophys. Biomol. Struct.* **27**, 259–286.)

ribonucleotides to deoxyribonucleotides. In the enzymes from different sources, the presence of free-radical intermediates on side chains of the amino acids tyrosine, tryptophan, cysteine, and even glycine has been demonstrated by ESR. ESR studies of tyrosine radicals, in this system and also in electron-transfer membranes, show that the unpaired electron density at the various carbon atoms of the tyrosine aromatic ring is fine-tuned by hydrogen bonds to the phenolic oxygen and by the protein environment. ESR spectra also provide information about side-chain torsion angles of the tyrosines giving rise to radicals. Figure 2 gives examples of EMR spectra of tyrosine radicals of ribonucleotide reductases from several sources.

In other proteins, tyrosine radicals participate in the mechanisms of cytochrome oxidase (mitochondrial respiratory complex IV), cyclooxygenase and other heme enzymes. In other proteins, glycine radicals have functional roles in lysine 2,3-aminomutase, pyruvate formate-lyase, and benzylsuccinate synthase. Enzyme-bound substrate and cofactor radical intermediates have also been characterized in enzymes dependent on S-adenosyl methionine, adenosylcobalamin, and arachidonic acid. It is often useful to use isotopic labeling with nuclei having magnetic moments (^{2}H, ^{13}C, ^{15}N, ^{17}O) in the effort to identify the radical site in an enzyme intermediate.

2.2 Paramagnetic Metal Ions in Biology

All metal ions containing unpaired electrons (paramagnetic ions) are, in principle, subjects for study by ESR, but the experimental conditions are quite varied. The paramagnetic ions in proteins, commonly studied by ESR, include manganese^{2+}, copper^{2+}, iron^{3+}, occasionally iron^{2+},

nickel^{3+}, vanadyl (V = O^{2+}), and cobalt^{2+}. The conditions for the spectroscopy differ drastically depending on which metal is the subject of study. Manganese ions are sometimes detected with high sensitivity in solutions at room temperature. However, detection of ^{17}O-threonine sidechain ligands to manganese in p21 *ras* required both low temperature and high-frequency ESR to give optimum results. Copper sites also can be detected at room temperature, but sensitivity is improved by conducting the ESR experiments at liquid nitrogen temperature or lower. Studies of iron are almost always done at temperatures near that of liquid helium. The two primary reasons that low temperature is used in metal ion ESR are that relaxation times are too fast for room temperature studies and the signal intensity increases inversely with temperature. The pulsed ESR methods ENDOR and ESEEM are chosen to detect nuclei such as nitrogen or hydrogen bound to, or near, metal ion sites.

Quantitative evaluation of the number of unpaired spins in different sites within a complex biochemical electron-transfer system can be made by ESR and associated studies. For experiments of this type, both calculations of the theoretical spectra and a multifrequency approach in the experiments are needed for interpretation. Recent advances in high-frequency ESR provide improved resolution in samples with multiple ESR-detectable metal sites. For example, Fig. 3 shows a high-frequency ESR spectrum of a frozen solution of copper ion in the site normally occupied by iron in lactoferrin.

The copper spectrum, spread over the field region from ~2.9 to 3.3 T, is well separated from the six-line signal of a manganese impurity near 3.4 T. At lower ESR frequencies, the manganese signal is superimposed on the central portion of the copper signal. Also notable in the high-frequency ESR spectrum shown (Fig. 3) is that the portion (at 2.9–2.95 T) of the spectrum arising from molecules with a unique axis aligned close to the magnetic field direction is well separated from the portion (at 3.2–3.3 T) arising from molecules in which this axis is perpendicular to the field. Additionally, the

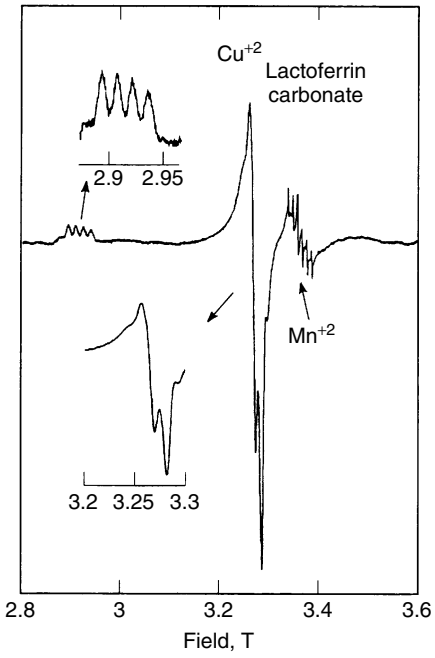

Fig. 3 High-frequency ESR spectrum of dicupric lactoferrin. The spectrum was recorded at 40 K and 94.1 GHz. The two regions from which significant information can be obtained are amplified in insets on the left. The feature on the right is the ESR signal from an impurity of manganese ion in the sample. (Reprinted with permission from Gaffney, B.J., Maguire, B.C., Weber, R.T., Maresch, G.G. (1999) Disorder at metal sites in proteins: a high frequency EMR study, *Appl. Magn. Res.* **16**, 207–222.)

splitting of these regions into four features arises from interaction of the unpaired electron with the four nuclear spin states of the copper nucleus. For copper proteins, very low-frequency EPR is also useful in revealing how many nitrogen ligands to the metal there are. This approach, as well as pulsed ESR, helped elucidate the nature of multiple copper binding sites in the prion protein (PrP), for example.

2.3 Protein Complexes with Nitric Oxide (NO)

Nitric oxide (NO) is a paramagnetic gas and molecular adducts of NO in solution give ESR signals that are employed to determine the pathway of nitric oxide transfers in proteins or the location of NO in tissues by *in vivo* ESR imaging. The characteristic ESR signal of some NO complexes is three lines, broader but otherwise similar to the spectrum shown in Fig. 1(c). When the ^{15}N isotope (nuclear spin states $\pm 1/2$) is incorporated in NO, the ESR spectrum simplifies to two lines. In an NO complex with iron, copper or other metals in proteins, broader signals with no resolved hyperfine splitting may or may not be observed. Three-line hyperfine splitting is seen in NO complexes with 5-coordinate ferrous heme iron, with the NO spin traps: ferrous ion chelated with dithiocarbamate derivatives, and with diverse iron-sulfur-dinitrosyl species *in vivo*.

NO is often used biochemically as an oxygen mimic, but it binds more tightly to metal centers than O_2 does and may alter other ligand geometries. When a single NO combines with ferrous iron, an ESR-detectable complex is formed. The spin 1/2 of NO combines with the even spin (spin = 0 or 2) of ferrous iron to give half-integer spin for the complex (spin = 1/2 or 3/2). Generally, half-integer spins yield well-resolved ESR spectra, whereas spin = 0 is not paramagnetic, and spin = 2 usually does not give resolved signals.

The strength of the Fe–NO interaction with iron in hemoglobin is demonstrated under conditions in which hemoglobin binds NO preferentially at the α-subunits; here, NO acts transaxially to cleave the proximal iron-His bond. ESR spectra of the resulting five-coordinate α-subunit heme have three resolved peaks from ^{14}N-hyperfine interactions. A similar spectrum of the five-coordinate NO complex with heme in myoglobin is shown in Fig. 4.

In contrast, when NO is in a six-coordinate complex with ferrous heme, a broad ESR signal, without hyperfine, is observed. NO activation at heme in guanyl cyclases also involves breaking an Fe-His bond, and the NO-Fe complex is ESR detectable. Interaction of NO or nitrite with oxyhemoglobin, or with methemoglobin, leads to a third species, S-nitrosyl hemoglobin. NO also reacts with

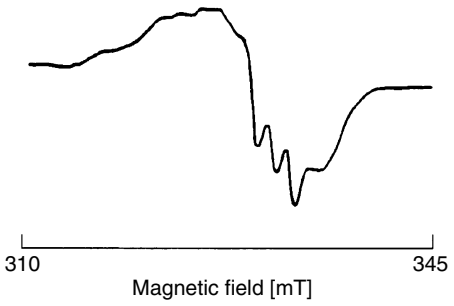

Fig. 4 The ESR spectrum of deoxymyoglobin to which nitric oxide (NO) gas was added. The spectrum was recorded at 77 K and a frequency of 9.1 GHz. (Reprinted with permission from Singel, D. J., Lancaster, J. R. Jr., (1996) *Methods in Nitric Oxide Research*, Feelisch, M., Stamler, J. S. (Eds.) John Wiley & Sons Ltd Ch. 23, pp. 341–356.)

the iron in iron-sulfur proteins. In the case of aconitase, one iron of the 4Fe-4S is lost upon reaction with NO and ESR signals of a protein-bound iron-$(NO)_2$ complex can be seen. This complex is likely an intermediate in the conversion to 3Fe-4S apoaconitase.

2.4 Factors Directing Electron Flow in Energetic Membranes

Mitochondrial and photosynthetic membranes are rich in species giving ESR signals during electron transfer. The full range of recent chemical bonding theory and ESR instrumentation is brought to bear in determining the electron-transfer pathways through the multiple intermediates. ESR studies provide electronic structures of intermediates in electron-transfer pathways, including electron spin density around the ring of an aromatic radical and the overlap of electron orbitals between two paramagnetic intermediates. This information is essential for determining how the surrounding protein matrix influences the path that electrons follow from one paramagnetic intermediate to another. Key electron-transfer species that are observed by ESR methods are summarized in Table 1. The list is not comprehensive. ESR examines the species listed either individually, or in pairs.

2.4.1 ESR Studies of Photosynthesis

The components of photosynthetic electron-transfer pathways, chlorophylls, quinones, and metal ions, are selected for ESR studies by preparations that include optical excitation, selective depletion of some components, and molecular biology. Because electron transfer can be primed by optical excitation in the preparations, it is possible to trap very short-lived intermediates by optical excitation of low-temperature glasses. High-frequency ESR is applied in some cases to improve resolution of ESR spectral components, much as higher frequency NMR gives better resolution of different nuclei (see also Sect. 2.2). In bacterial reaction centers, electrons flow from an excited bacteriochlorophyll dimer to bacteriopheophytin, to quinone A (Q_A), and to quinone B (Q_B). The electronic interactions between these sites are influenced by a $^{2+}$Fe ion on the pathway.

Tab. 1 Some Components of Energetic Membranes Detected by ESR.

Component	*Abbreviation*	*Membrane*
Donor cation (a chlorophyll)	$BChl_2$, $P_{700}{}^{+\bullet}$ chlorophyll b, $P_{680}{}^{+\bullet}$	RC, PS I, PS II
Reduced quinones	$Q_A{}^{-\bullet}$, $Q_B{}^{-\bullet}$, $Q^{-\bullet}$	RC, PS I, PS II
Iron-sulfur clusters	$[2Fe2S]^{-1}$, $[4Fe4S]^{-1}$, or $[4Fe4S]^{+3}$	PS I, Fd, Cplx III
Manganese clusters	Mn(III) + 3 Mn(IV)	PS II-S_2
Tyr radical	$Tyr^{+\bullet}$	PS II
Ferric heme	heme-Fe^{3+}	Cplx IV
Copper	Cu^{2+}	Cplx IV

Notes: RC: reaction center of purple bacteria; PS I: photosystem I of plants, cyanobacteria, green sulfur bacteria, and algae; PS II: photosystem II of plants, cyanobacteria, and algae; Fd: ferrodoxin; Cplx: one of the electron-transfer complexes of mitochondria; PS II-S_2: the S_2 intermediate of PS II photocycle.

Distances between electron sites on the intermediates, and the term describing electron exchange interactions between them, have now been tabulated for the bacterial system. Good agreement between these ESR measurements and electron-transfer theory is observed.

In plant photosynthetic membranes, ESR is used to examine the manner in which electrons flow ultimately into the photosynthetic oxygen-evolving complex that contains varied numbers of unpaired electrons associated with a cluster of four manganese atoms. A tyrosine radical abstracts an electron and a proton from the manganese cluster and water in steps, leading to oxygen evolution. Determining how the protein environment influences the electronic structure of the tyrosine radical and its coupling to the manganese cluster are subjects of study by the pulsed ESR techniques ESEEM and ENDOR.

2.4.2 ESR Studies of Respiratory Enzymes

In the synthesis of ATP, the mitochondrial respiratory chain employs many of the same cofactors as photosynthetic membranes, although the electron/proton transfers are not photochemically initiated. Instead, reductants or oxidants are used to isolate states with unpaired electrons. ESR contributes to understanding the electronic structure of the oxidized or reduced cofactors. In one example, ESR studies reveal an asymmetric hydrogen-bonding environment for a ubisemiquinone ($Q^{-\bullet}$) bound to bacterial quinol oxidase (QOX), bo_3. QOX is structurally and functionally related to mammalian cytochrome oxidases. In these experiments, quinones, ^{13}C-labeled individually at the carbonyl carbons, were substituted for the natural ubiquinone in QOX by detergent extraction and reconstitution. Control ESR experiments (^{14}N-ESEEM) demonstrated that the reconstituted, labeled quinones had the same hydrogen-bonding environment as native quinones. The line widths of the high-frequency ESR spectra from ^{13}C-labeled quinones differed, depending on whether the label was located on carbonyl-1 or -4. This shows that the unpaired electron spin distribution is asymmetric in the ubiquinone radical when the radical is bound to its cognate protein. The spin distribution is, in turn, related to an asymmetric hydrogen-bonding environment for the protein-bound $Q^{-\bullet}$.

3 ESR Probes of Biological Structure and Function

3.1 Spin Labeling

Nature does not always provide a free-radical ESR subject at a site of interest. Spin labels are stable, paramagnetic molecules that can be easily tailor-made by organic synthesis to provide selective structural and dynamical information via ESR spectroscopy. Most spin labels are nitroxide molecules. An advantage of spin label ESR studies is that they can be carried out at physiologically relevant temperatures and they are therefore sensitive to molecular motion. Nitroxide labeled nucleic acids, lipids, and enzyme cofactors are among the variations of spin label analogs that have been made. The largest area of applications to proteins is a molecular biology–based approach called site-directed spin labeling (SDSL) for studying the dynamics, folding, and structure of proteins.

3.1.1 Dynamics of Proteins, DNA, and Membranes

The effects of motion of a spin labeled macromolecule can be observed indirectly,

as averaging of features in the ESR spectrum or directly, by time domain ESR experiments. Effects of motion on a spin label ESR spectrum arise because the unpaired electron in the nitroxide molecule is in an asymmetric environment that renders the magnetic interactions sensitive to the orientation of the spin label in the field. When the spin label is rigidly attached to a larger molecule, ESR spectra reflect the motion of the macromolecule. The frequency of the particular ESR spectrometer used and the details of the detection scheme determine the timescale of motions that can be detected using spin label ESR. Motions occurring on timescales from milliseconds to fractions of a nanosecond have been measured. Applications in the area of dynamics include resolving spectra from distinct motional states of muscle, detecting time-dependent structural changes in bacteriorhodopsin, studies of the persistence length for DNA bending and measurements of anisotropic motion of lipids in membranes.

Figure 5 illustrates the sensitivity of ESR to spin label motion in an isotropic paraffin liquid and in a lipid membrane. The nitroxide molecules pictured have shapes that are roughly a sphere, a rectangular prism, and a long cylinder. The three peaks of equal intensity in ESR spectra of the spherical molecule, TEMPO (2,2,6,6-tetramethyl-4-ketopiperidine-1-oxygl), rotating in paraffin are characteristic of isotropic motion. The other spin labels move in paraffin with only slightly different rates about x, y, and z molecular axes (slight broadening of the third peak results). In contrast, motion of the larger spin labels is quite restricted in a lipid bilayer, as indicated by the broader ESR spectra. ESR of the fatty acid spin label reveals that the molecule rotates about the bilayer normal and has some internal flexibility. The lower spectrum from TEMPO in membranes was obtained from a more dilute lipid preparation than the upper one. The additional peak results from some TEMPO in water.

3.1.2 Site-directed Spin Labeling (SDSL)

In SDSL, a reactive nitroxide (e.g. a methanethiosulfonate) reacts with a cysteine side chain that has been placed at one or more selected sites in a protein by site-directed mutagenesis. Figure 6 shows the reaction scheme most often used in the SDSL approach. Secondary structure determination is one application of SDSL, and the approach involves stepwise substitution of nitroxides on a protein structural element. The surface exposure of the SDSL sites is determined through magnetic effects of oxygen or paramagnetic ions on ESR spectra. Interresidue distances between two spin label sites can also be determined as illustrated in Fig. 7 for phage T4 lysozyme. The overall structure of the protein shown in (a) indicates the close proximity of the two spin label side chains at residues 3 and 71. The inset (b) shows ESR spectra of folded, di-spin labeled phage lysozyme (bottom) and the same protein unfolded in urea (top). Spin labels separated by 10 to 25 Å give broadened spectra from which the interresidue distance can be determined. Once a protein derivative has been prepared with two interacting spin labels, spectral changes may be employed to determine refolding kinetics as illustrated in Fig. 7(c). Interresidue distances in membrane proteins, such as rhodopsin, are estimated by the complementary techniques of cysteine-scanning mutagenesis and paired site-directed spin labeling.

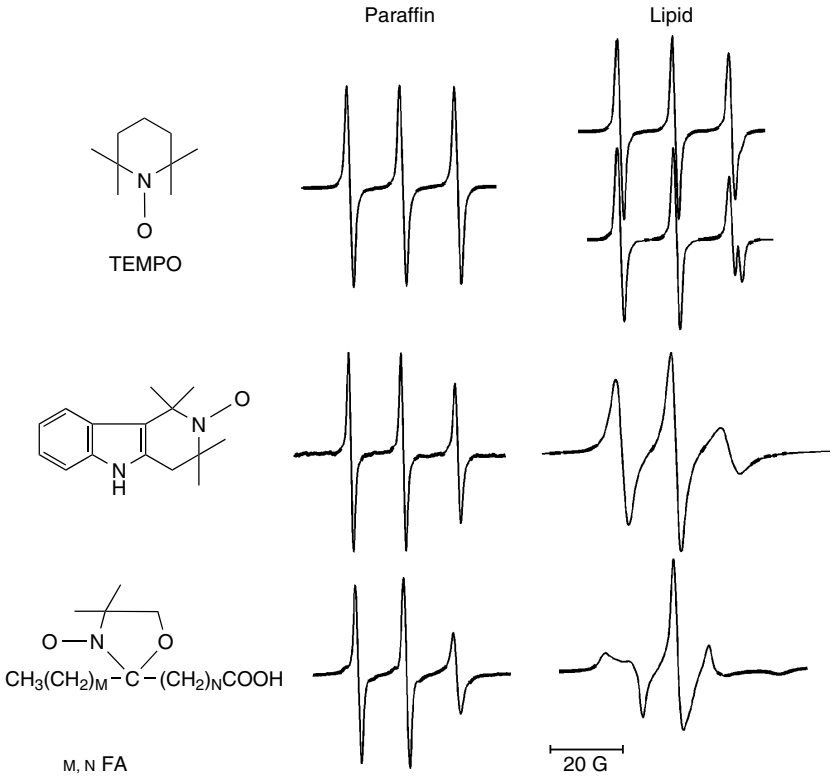

Fig. 5 The effects of restricted motion on the ESR spectra of molecules of different shapes and sizes. The spectra in the left column were obtained using a liquid paraffin solvent (isotropic) and those in the right column were with lipid bilayers (anisotropic fluid), both at 37 °C. Two concentrations of lipid were used for the upper right pair of spectra, a higher concentration in the top and a lower one below. (Redrawn with permission from Gaffney, B.J., Chen, S.C. (1977) *Methods in Membrane Biology*, Korn, E.D. (Ed.) Plenum Press, New York, Vol. 7, pp. 291–353.)

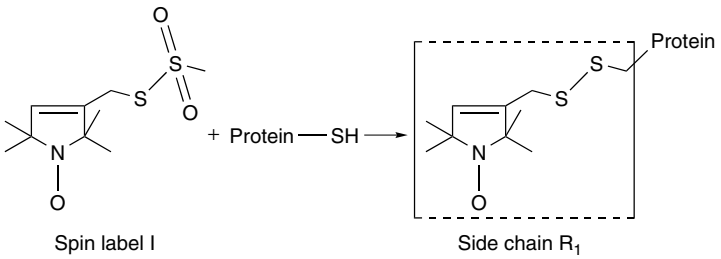

Fig. 6 Introduction of a site-directed spin label. A methanethiosulfonate spin label reacts with the natural, or genetically engineered thiol side chain of a protein to give a site-directed, spin-labeled protein. (Redrawn with permission from Hubbell, W.L., Mchaourab, H.S., Altenbach, C., Lietzow, M.A. (1996) Watching proteins move using site-directed spin labeling, *Structure* **4**, 779–783, Fig. 1.)

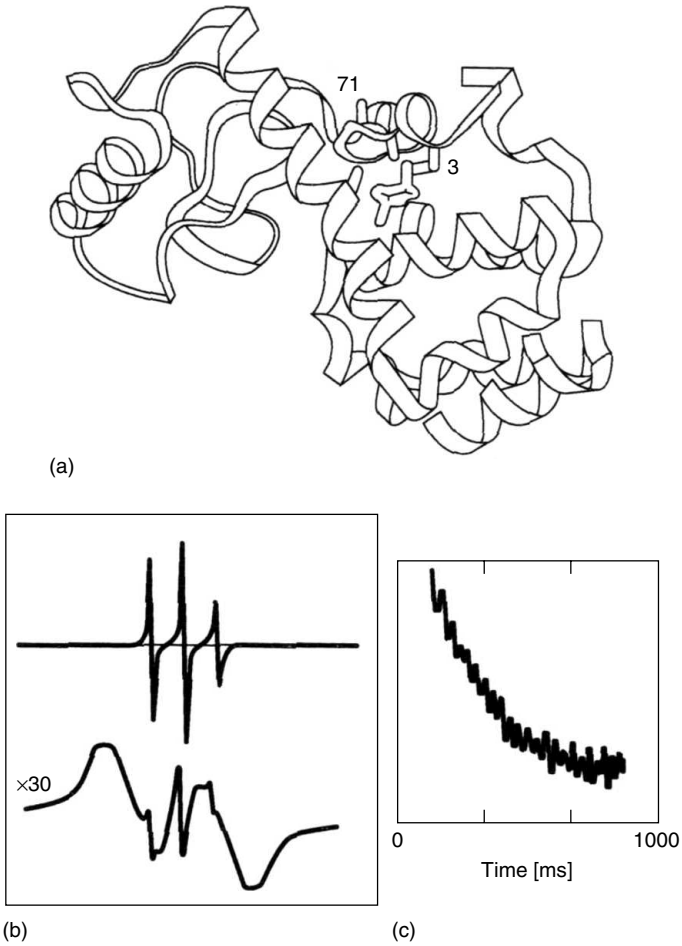

Fig. 7 Spin labeling of phage T4 lysozyme. The structure of a mutant T4 lysozyme in which two free cysteine residues were introduced (I3C and V71C) after reaction with spin labels is shown after reaction with spin labels, as in the scheme of Fig. 6. The proximity of the spin labels leads to the broad ESR spectrum shown in red in the inset (b, lower). The ESR spectrum of the same sample unfolded in urea is sharp and shows little interaction between spin labels (b, upper). The time-resolved rate of refolding can be followed by ESR (c). (Reproduced with permission from Hubbell, W.L., Mchaourab, H.S., Altenbach, C., Lietzow, M.A. (1996) Watching proteins move using site-directed spin labeling, *Structure* **4**, 779–783, Fig. 5.)

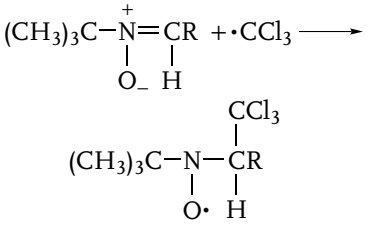
3.2 Spin Trapping

Detection of free radicals that occur transiently in cells places perhaps the most challenging demand on ESR, because the radicals have short lifetimes and are of low abundance. Free radicals can be detected indirectly by trapping them to give a longer-lived, secondary radical

in the technique called spin trapping. This technique usually employs nitroxide synthetic precursors to trap unstable free radicals such as xenobiotic radicals, superoxide, and hydroxyl radical. When there is one hydrogen on the carbon next to the nitrogen of a spin trap, the hyperfine splittings in ESR signals of the trapped radical are sensitive to whether an oxygen- or carbon-centered radical was trapped. The scheme below gives the chemistry of a spin trap nitrone reacting with trichloromethyl radical, derived from carbon tetrachloride. This approach has been used to trap similar radicals from halothane *in vivo*.



Spin traps can exhibit therapeutic effects *in vivo*, for instance, by inhibition of lipoprotein oxidation. Immunological methods are also used to detect spin-trapped sites on biomolecules.

3.3 ESR Imaging

Relaxation of spins is a dominant theme in ESR because the lifetimes of spins excited to upper energy levels are typically of the order of microseconds. A window on biological rates from 10^9 to about 100 s^{-1} results from the effects of magnetic relaxation on ESR spectra. Collision frequencies of molecules in solution, at biological concentrations, are in the range suitable for ESR relaxation responses. Relaxation of a spin probe depends on the frequency of collisions with paramagnetic oxygen. The simplest manifestation of relaxation is a change in line width of the ESR signal. This interaction is exploited to create images of oxygen levels in tissues. Spin traps selective for NO provide another basis for ESR imaging.

3.3.1 ESR Imaging of Oxygen in Tissues

The ESR spectrum of dissolved oxygen is not suitable for sensitive detection, but the ESR line width of a spin probe does respond to physiological concentrations of oxygen. EPR imaging, a technique under development, relies on spin probe relaxation to provide information about spatial distribution of oxygen in tissues, for instance, in tumors. In a sense, ESR imaging of oxygen concentration in tissues is a spin trap experiment in which the magnetism of oxygen is ''trapped'' through its magnetic, but not chemical, interactions with a stable spin probe. The degree of broadening of the ESR signal is transformed into an image.

A direct comparison of images of the same mouse tumor obtained by ESR imaging (EPRI) and by MRI has been made. In the experimental design, the leg bearing the tumor is centered in an ESR resonator or an MRI coil for the two imaging modalities. Paramagnetic reagents are applied intravenously in the ESR experiment, at a level similar to that used for MRI contrast agents. Both stable trityl (triphenylmethyl) radicals and nitroxides are used in EPRI, but the extremely narrow signal from trityl probes provides spatial resolution of about 1 mm in a tumor of $7 \times 7 \times 10$ mm. An ESR spectrum of the reagent in each pixel is obtained (spectral-spatial imaging). Separate calibration experiments demonstrate linear response of the ESR line width to oxygen concentration in the range 0 to 75 torr $\pm \sim$3 torr. ESR and MRI obtain

comparable images of regions of the spatial distribution of oxygen, but the ESR experiment has the advantage that the oxygen concentrations are measured quantitatively. ESR imaging is performed at low frequency because the higher frequencies used in most ESR spectroscopy cannot penetrate far into wet tissues.

3.3.2 ESR Imaging of NO

A focus of ESR imaging has been to examine formation of NO from nitrite in ischemic rat hearts. With increasing durations of ischemia, the myocardial pH drops and this facilitates reduction of nitrite to NO. For example, both *ex vivo* and *in vivo* experiments are conducted in hearts loaded with ~1 mM nitrite and the NO spin trap, ferrous (N-methyl-D-glucamine dithiocarbamate)$_2$. By comparing pH measurements from ^{13}P-NMR with the quantity of trapped NO in the heart, significant NO formation from nitrite is demonstrated. Control experiments with inhibitors of nitric oxide synthase (NOS) and cytochrome oxidase augment these experiments.

3.4 Long-range Distance (6–60 Å) Measurements by ESR

The influence by one spin on the relaxation of another can also extend over a distance. In practice, this makes it possible to measure, by ESR, the distance between two paramagnetic centers, separated by up to 60 Å, in a biomolecule.

The advantages of using ESR methods to measure selected nonbonding distances in biomolecules are that the measurements are usually free of paramagnetic sites other than those involved in the measurement, and the sample can be opaque or semisolid. Recently, methods for ESR distance measurement have been tested and refined. The choice of a method depends on the relative relaxation rates of the two paramagnets between which a distance is sought. Generally, organic radicals such as spin labels and tyrosine radicals have spins with slow relaxation rates, whereas metal ion spins relax faster. Thus, specific methods are chosen for cases in which a slow relaxer is paired with either a second slow, or second fast relaxing paramagnetic species. The range 6 to 60 Å is a conservative estimate of distances that can be determined by ESR studies of two interacting paramagnets.

Electroporation
Same as electropermeabilization.

Electrofusion
Using a pulsed electric field to fuse two adjacent cells.

Electroporation is a phenomenon in which the cell membrane is temporarily permeabilized by exposure to an intense electric field. This phenomenon can be used to introduce a variety of exogenous molecules, particularly DNA, into living cells. Electrofusion is a related phenomenon by which neighboring cells can be induced to fuse by applying a pulse of electric field. Both electroporation and electrofusion are related to the electrical breakdown of the cell membrane. Electroporation is now a principal method of gene transfer, for both prokaryotic and eukaryotic cells. Electrofusion is found to be the most efficient method of cell fusion and has important uses in agriculture and in the production of hybridomas.

1 Principles

1.1 Electric Field–induced Membrane Breakdown

The phenomenon of electroporation has been known for some time; studies can be traced back to the early sixties. The application of electroporation in molecular biology, however, is relatively recent. The first report of using electroporation for gene transfer appeared only in 1982.

Electroporation is the result of membrane breakdown induced by an applied electric field. Suppose a spherical cell with diameter r is exposed to an external electric field for a time period t. The cell membrane will develop an induced membrane potential V_m according to the following equation:

$$V_m = 1.5Er\cos\theta\{1 - \exp(-t/\tau\tau_c)\} \quad (1)$$

where E is the field strength, θ is the angle between the field and the normal of the membrane, and τ_c is the relaxation time of the cell. For a typical biological cell, τ_c is approximately equal to

$$\tau_c = rC_m(\rho_i + 0.5\rho_o) \quad (2)$$

where C_m is the unit capacitance of the cell membrane and ρ_i and ρ_o are the resistivity of the cytoplasm and the external medium respectively. For small cells, such as red blood cells, τ_c is on the order of 1 μs. Then, when the external electric field is applied for a sufficiently long time period, say 20 μs, the induced membrane potential will reach the steady value

$$V_m = 1.5Er\cos\theta \quad (3)$$

From this equation, it is apparent that the induced membrane potential is not uniform across the entire cell membrane. The induced membrane potential is highest at

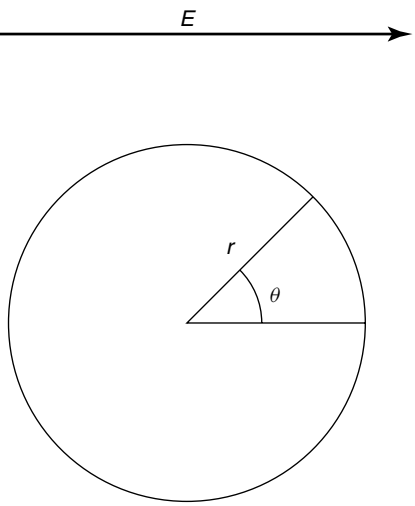

Fig. 1 Schematic diagram showing a spherical cell exposed to an external electric field, *E*.

places where the membrane faces the poles of the electric field (Fig. 1).

The above analysis holds true so long as the cell membrane remains intact and its electrical properties do not change. When the external field strength is so high that the induced membrane potential exceeds a threshold potential, V_{th}, the bilayer membrane will experience an electrical breakdown; the cell membrane can no longer maintain its structural integrity and becomes permeable. This phenomenon is called *electroporation* or *electropermeabilization*. For most cells, the threshold potential is typically on the order of 0.5 to 1 V, which is about 10 times larger than the normal resting potential of an animal cell. The occurrence of electrical breakdown is related to the fact that the cell membrane is a very thin structure. The insulating property of the cell membrane depends on its lipid bilayer, which is only 5 nm thick. When the potential across the cell membrane is increased to 1 V, the electric field within the bilayer reaches 2×10^6 V cm^{-1}. The membrane cannot withstand an electric field of such magnitude and it undergoes a dielectric breakdown.

When the cell membrane is permeabilized by an applied field, molecules that normally could not penetrate the membrane can now pass through easily. These molecules include ions, metabolites, carbohydrates, proteins, nucleic acids, and others. Some of the molecules that enter the cell during the electropermeabilized state could be very large. It has been reported that DNA molecules of sizes up to 150 kbp can be taken up by electropermeabilized cells. The uptake of these very large molecules, however, may involve some complex processes. As for small molecules, such as small carbohydrates or proteins of low molecular weight, it is evident that they can enter the cell by simple diffusion through the permeabilized cell membrane.

If the external electric field is not excessively high, the electropermeabilized cell can recover by resealing its membrane after the external field is removed. Using a model membrane, such as a lipid bilayer, the processes of electroporation

and recovery can be studied by monitoring the changes in the electrical properties of the membrane in response to the application of the external field. For the lipid bilayer, the electroporation process involves three distinct stages:

1. *Nonpermeabilized state*. This is the state of the membrane before the external field is applied. The conductance of the membrane is extremely low.
2. *Permeabilized state*. When the external field is applied, the induced membrane potential (V_m) builds up exponentially. When V_m approaches the threshold potential (V_{th}), the conductance of the membrane increases drastically, indicating that the membrane has become permeabilized to certain ions.
3. *Recovery state*. If the external field is applied only for a brief period and the field strength is not too high, the bilayer will recover by gradually resealing itself after the external electric field is turned off. In this case, the bilayer membrane is said to experience a *reversible breakdown*. The recovery process can be monitored by observing an exponential decrease in the membrane conductance following the termination of the applied field. This recovery process appears to be very rapid; the time constant is generally on the order of submilliseconds. If the external field is applied for too long or if the field strength is too high, the bilayer will not be able to recover and it will rupture even after the applied field is removed. In this situation, the membrane is said to undergo a process called *irreversible breakdown*.

In electroporation of real cell membranes, the situation is more complicated. There is evidence suggesting that the electroporation process may involve several substages. Furthermore, the membrane may undergo secondary structural changes following the removal of the external field. Thus, when an electric field is applied to electroporate cells, the cell membrane may undergo at least four different stages of change:

1. *Nonpermeabilized state*. Before the external field is turned on, the cell membrane is in its normal intact state.
2. *Permeabilized state due to primary structural changes*. After the external field is applied, the induced membrane potential quickly reaches the threshold potential. As a result, the membrane experiences an electrical breakdown and undergoes a structural change to become permeabilized. This electric field–mediated membrane breakdown is commonly referred to as *primary structural changes*.
3. *Permeabilized state due to secondary structural changes*. Once the cell membrane becomes permeabilized, molecules can pass through the membrane to enter or leave the cell. Such flow of material can induce further structural changes in the membrane, making it even more permeable to other molecules. Furthermore, breakdown of the membrane structure in a local region may affect the stability of the membrane structures in neighboring regions and thus could further enlarge the membrane pores. These secondary structural changes can continue even after the removal of the external electric field.
4. *Recovery state*. After the external field has been turned off and the forces causing the pores to expand have subsided, the membrane will repair itself and start to reseal. The mechanism of membrane healing is not yet well understood. However, it is well known that a cell

can repair its own membrane following puncture or scratch. This recovery process takes considerably longer than in the case of a lipid bilayer model membrane. Moreover, the resealing process itself is believed to involve several substages. The larger membrane pores may reseal first, with a time constant on the order of seconds. They, however, do not reseal completely but reduce into residual pores that may linger for considerably longer times. Depending on the cell type, the resealing process may take several minutes to half an hour at room temperature. At lower temperatures, such as at 4 °C, it will take even longer.

The structure and properties of the electric field–induced pores have been investigated actively in the last two decades. The results are still far from complete. There have been different suggestions about the structures of these membrane pores. Some thought that these pores might appear in the form of cracks in the membrane. A few others proposed that they are craterlike round pores. There are also conflicting estimates of the size of the pores. One study concluded that, on the basis of examination of transport properties of the electropermeabilized cell membrane to carbohydrate molecules of different sizes, the membrane pores are very small, with diameters on the order of 1 nm. Another group examined the size of labeled molecules that can be loaded into red cell ghosts and concluded that the size of the membrane pores could reach 10 nm. However, in view of the fact that large macromolecules such as DNA can pass through the cell membrane during the electropermeabilized state, it is suspected that the electric field–induced pores may be significantly larger. We recently used a rapid-freezing electron microscopy (EM) technique to examine the dynamic changes in membrane

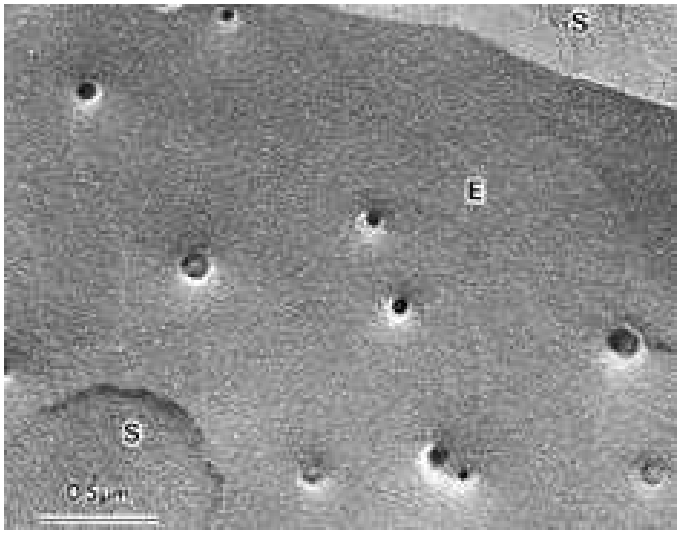

Fig. 2 External membrane face (labeled "E") of an electro permeabilized human red blood cell frozen at 40 ms after the application of an electrical pulse. The frozen extracellular medium is labeled "S."

structure during the electropermeabilized state (Fig. 2). Large volcano-shaped porelike structures with diameters up to 100 nm were observed in the freeze-fractured membrane. Thus, the size of ''electropores'' could be much larger than that indicated earlier.

When we examined the membrane structure of cells frozen at different times after application of the electric pulse, we found that the membrane pores induced by the electric field underwent significant changes with time. The structure of the red cell membrane frozen at $t = 1$ ms appeared to be smooth and without any unusual structural changes, just like the control membrane. (Here ''t'' is the time delay between the electric pulse and the time when the specimen was frozen). These observations suggest that, if electropores were formed in the first millisecond following application of the electric field, the diameter of these early pores must be very small (less than the resolution of the freeze-fracture EM, about 2 nm). The earliest time at which we could detect any significant structural changes in the cell membrane was at $t = 2.5$ ms, where deep porelike membrane openings (20–40 nm in diameter) were found in a few E-face membranes of the electropermeabilized red cells. At a later time ($t = 20$ ms), circular membrane openings became more abundant, and the size of the openings appeared to increase. At $t = 40$ ms, porelike membrane openings could be observed in almost all cell membranes examined, and their diameters had expanded to the range of 20 to 120 nm (Fig. 2). At $t = 0.2$ to 1.7 s, circular membrane openings similar to those observed at $t = 40$ ms could be found in most red cells. At $t = 5$ s, the deep porelike structures had almost disappeared and were replaced by numerous pitlike indentations in the membrane, which may be remnants of previous membrane evaginations. These pits might still have an opening in their centers, but such an opening must be very small. Since it was not possible to resolve the shape of such openings with freeze-fracture EM, their diameter had to be less than 3 nm.

On the basis of the time-dependent study of membrane structure using rapid-freezing EM, we believed that the membrane pore induced by the electric field was a dynamic structure whose shape and diameter underwent rapid change with time. The dynamic change in electropores at various stages is conceptually summarized in Table 1.

Thus, the different estimates of pore size reported in the literature may be

Tab. 1 Dynamic change in membrane pores in red blood cells during electroporation.

Time after pulsing	*State of the cell membrane*	*Estimated pore size*
<0 s	Intact membrane	<0.2 nm
0.001–0.01 s	Pore creation due to electrical breakdown	1–10 nm
0.01–1 s	Pore expansion due to material flow	10–100 nm
1–10 s	Membrane starts to reseal; pore shrinking	1–10 nm
0.1–30 min	Membrane continues to reseal; existence of long-lasting residual pores	1 nm
>30 min	Membrane fully recovered	<0.2 nm

partially due to the differences in measurement techniques and partially related to the dynamic nature of the pores, which can appear differently at different stages. The large porelike structures observed in the rapid-freezing EM study may represent transient membrane pores through which DNA molecules can enter the cell. The small pores found in the transport study of carbohydrates, on the other hand, may represent the long-lasting residue pores at the recovery stage. Since the measurements of carbohydrate transport require minutes, most of the large membrane pores would have undergone partial resealing during the measurement period.

1.2 Uptake of Exogenous Molecules during Electroporation

Molecules with a variety of shapes and molecular weights can be taken up by cells during the electropermeabilized state. These molecules include DNA, RNA, proteins, drugs, metabolites, ions, molecular probes, and so on. Depending on the size and charge of the transported molecules, the process of molecular uptake can be different. For small molecules, they could enter cells by simple diffusion during the electropermeabilized state. In studies using either lipid vesicles or red cell ghosts, it has been demonstrated that loading of small molecules, including ions, carbohydrates of low molecular weight, or dyes, during electroporation can be explained simply on the basis of a diffusion model. The uptake of larger molecules such as DNA is more complicated; the process is believed to involve a number of sequential steps. At this point, the exact mechanism of DNA uptake during electroporation is not yet clearly understood, but there is evidence suggesting that the following processes are involved:

1. Before application of the external electric field, a certain fraction of DNA molecules may have already been bound to the cell surface. Such binding could be a required intermediate step for DNA to enter the cell when the cell membrane is electropermeabilized.
2. Application of an external field creates pores on the cell membrane. Some of these pores may have a transient opening that is large enough to allow DNA molecules to pass through.
3. Through an electrophoretic process, the negatively charged DNA molecules may be driven toward these pores, and they enter the cell by the applied electric field.
4. Alternatively, the entire DNA molecule may not actually enter the cell during the electropermeabilized state. Instead, the applied electric field may disrupt the membrane structure to create a phospholipid/DNA complex that would then stimulate the internalization of DNA by endocytosis.

The processes discussed above have been examined in a number of studies and are supported by some of the experimental results. For example, in some systems, the concentration of magnesium ions was found to have a significant effect on gene transfer efficiency. Such a finding may be explained on the basis of DNA binding to the cell surface. Several laboratories, including our own, found that, in order to have an effective gene transfer, DNA must be first added to the cell mixture before applying the electric field. This finding suggests that either the large transient pores have a very short life or DNA must be driven into the cell by the applied field. Using cultured cells grown on a filter

membrane, it was possible to examine the effect of the polarity of the electric field on gene uptake. We found that when DNA was applied on the cathode side, the gene transfection efficiency was much higher. Recently, it was reported that in a single-cell visualization study, fluorescent-labeled plasmids were observed to enter the electropermeabilized cell on the side facing the cathode. This finding suggests that DNA entry may involve an electrophoretic process. At present, however, the existing evidence cannot exclude the involvement of other processes, such as endocytosis.

1.3 Electric Field–induced Cell Fusion

One can apply a pulsed electric field not only to electropermeabilize cells but also to induce cells to fuse. When two neighboring cells are placed very close to each other, applying a pulsed electric field similar to that used in the electroporation process will induce these cells to fuse. This process is called *electrofusion*. The development of electrofusion has a slightly shorter history in comparison with electroporation. Induction of fusion of plant cells by electrical stimulation was first reported in 1979. Electrofusion of several other cell types was reported in the following years. Because of its many important applications, including cell hybridization, animal cloning, and generation of antibody-producing hybridomas, electrofusion quickly became a popular subject of study in the early eighties.

In order to induce cells to fuse, the cells must first be brought in contact with each other. There are a number of methods to achieve this.

1. *By mechanical means*. One can use a specially designed container so that cells are forced to aggregate in close proximity. Or, attached cells can be cultured side by side.
2. *By chemical means*. Cells can be coated with certain chemicals that bring the cells together. For example, one cell type can be coated with biotin while the other with avidin. Or, one cell type may express an antibody against a surface protein of its fusion partner. The immunoreaction would bring the proper pair of cells together.
3. *By dielectrophoresis*. This is probably the most elegant way to bring cells together for electrofusion. When a suspended cell is exposed to an external electric field, it develops an induced dipole moment in parallel to the field. Thus, under a weak electric field, suspended cells would tend to attract each other through the induced dipole–dipole interaction. They often form a long chain of cells (commonly referred to as a *pearl chain*). This process is called *dielectrophoresis* (Fig. 3). The external field used to produce dielectrophoresis is not limited only to a DC field but it can also be an oscillating field. For technical reasons, the dielectrophoresis field used in electrofusion is a continuous oscillating field with a frequency on the order of megahertz; the field strength is usually quite low, in the range of 10 to 20 V cm^{-1}. Such a low field is sufficient to bring about dielectrophoresis while not causing electropermeabilization.

It has been demonstrated in studies using red blood cells that, in electrofusion, two kinds of fusion can occur: ''membrane fusion'' and ''lumen fusion.'' In membrane fusion, only the membranes of the neighboring cells fuse, while the cytoplasm of the cells remain separate. In lumen fusion, the fusing cells truly fuse their cytoplasm to form a syncytium.

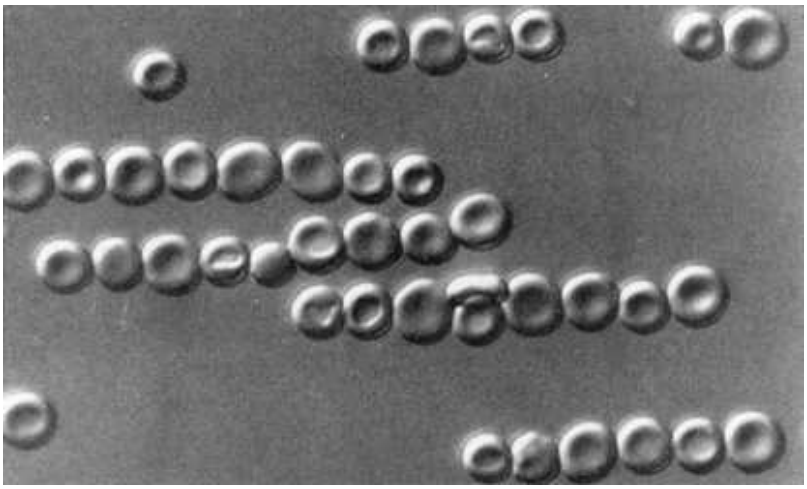

Fig. 3 Formation of pearl chains of human red blood cells, induced by applying a low-intensity AC field (200 V cm^{-1}, 60 kHz). (Reproduced from Chang, D.C., et al. ''Electroporation and Electrofusion Using a Pulsed Radio-Frequency Electric Field''. *In* Chang, D.C., Chassy, B.M., Saunders, J.A. and Sowers, A.E. (Eds.): *Guide to Electroporation and Electrofusion*. Academic Press, Inc. San Diego, CA (1992), p. 319.)

Membrane fusion can be observed using a hydrophobic dye such as DiI, which is selectively distributed in the membrane. If one mixes cells labeled with DiI with unlabeled cells, the dye will be seen to transfer from a labeled cell to an unlabeled cell when the membranes of the two cells fuse. Lumen fusion can be monitored by preloading one of the fusing partners with a fluorescent dye, such as FITC-conjugated dextran. It was discovered that, even after the cell membranes fuse, the lumens of the two cells may or may not fuse. In cell types other than red blood cells, most of the fusion products of electrofusion are of the lumen fusion type.

The time required to fuse two cells using electrofusion varies with the cell type. The electric field is usually applied for a very brief period, about a millisecond. In a few minutes after the application of the electrical pulse, fusion between neighboring cells can be seen. In red blood cells, the fusion process may be completed in about five minutes. For attached mammalian cultured cells, however, the fusion process may take many hours.

The mechanism of electrofusion is not fully understood at present. It is generally believed that the phenomenon of electrofusion is closely related to that of electroporation. In order to induce cells to fuse, the membrane structure of the two neighboring cells must be disrupted so that they can merge together. This electric field–induced disruption of the membrane structure could be very similar to that of the electropermeabilization process. In the literature, several models have been proposed to explain how the electric field may bring about cell fusion.

1. *Joining of electropores in the apposing membranes.* In the early model of electrofusion, it was suggested that when two cells are in close contact during the electroporation state, electropores on the apposing cell membranes may line

up with each other. During the membrane resealing process, the pores may merge to become a continuous intercellular channel; the apposing membranes now fuse at the rim of the merged pore. Such a membrane structure is unstable due to its sharp curvature. As a result, the merged pore expands quickly. This expansion will gradually lead to the fusion of the two cells.

2. *Electric field–induced compaction*. When cells are lined up to form a pearl chain, application of an intense electrical pulse would produce two major effects on the cell membranes. Besides breaking down the membranes, the applied electric field also induces a strong dipolar interaction between the adjacent cells. Such an interaction generates a strong attractive force between the apposing cells and forces the adjacent membranes to come together to make physical contact, which eventually leads to fusion.
3. *Weakening of the hydration force*. In this model, it is argued that there exists a strong repulsive force when two cells are brought into close proximity. This force is originated from the ordering of several water layers at the cell surface. When cells are brought into contact, their respective water layers repel each other. This repulsive force, called *hydration force*, is the major force that prevents spontaneous cell fusion. When an intense electric field is applied, it will disrupt part of the membrane structure and will partially destroy the orderly organization of the cell membrane. As a result, the ordering of the surrounding hydration layer will also be destroyed. The strength of the hydration force is greatly reduced, and the adjacent membranes of the two cells can now come into contact and subsequently fuse.

In the early studies of electrofusion, it was thought that, in order to fuse cells, cells must be first brought into contact before application of the intense electric field. Later experiments demonstrated that application of an intense electric field can induce fusogenic properties even in isolated cells. When cells are first exposed to an intense electric field and then brought together in the absence of the field, some of them can still fuse with each other. Such an electric field–induced fusogenic property was cited as supporting evidence for model #3 discussed above.

2 Techniques

2.1 Waveforms Used for Electroporation and Electrofusion

The external field used in electroporation or electrofusion is always applied in the form of a pulse. Such a pulse can have different shapes, or waveforms, which include (1) rectangular pulse; (2) exponential decay pulse; and (3) oscillating pulse (Fig. 4). In the early stage of development of electroporation and electrofusion, most of the studies used only rectangular pulses. The pulse width, or τ, was usually very short. The major requirement for the pulse width is that it must be longer than the relaxation time of the cell, which is typically on the order of microseconds. Another requirement is that the field must be applied long enough to allow the membrane to undergo an electrical breakdown. There is also a limitation on how long that τ is. In a study using EM to examine structural changes in electropermeabilized cells, it

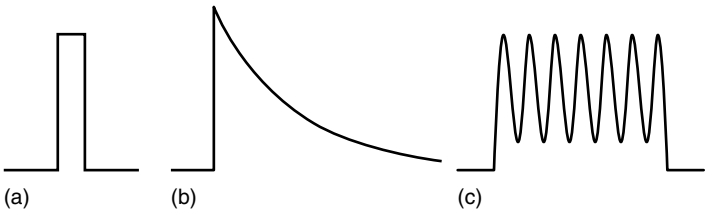

Fig. 4 Major types of waveforms used in electroporation and electrofusion: (a) rectangular pulse, (b) CD pulse generated by discharging a capacitor, and (c) DC-shifted RF pulse.

was shown that, when the pulse width was shorter than 20 μs, cells were more or less intact over a very wide range of applied field strength. If τ is much longer than 20 μs, however, the same field strength caused excessive cell damage. Thus, in most of the early works, the pulse width is usually very short, and the intensity of the applied electric field is relatively high, typically several kilovolts per centimeter for mammalian cells. To electroporate smaller cells, such as bacteria, the required field strength may be as high as 20 kV cm^{-1}.

Recently, the exponential decay pulse has become a more popular waveform for use in electroporation or electrofusion. This pulse is usually generated by discharging a large capacitor that is precharged to a high voltage, and it is thus frequently referred to as a *capacitor discharge (CD) pulse*. The advantage of using the CD pulse is that it requires only simple equipment to generate such a pulse. The disadvantage is that it is difficult to deliver multiple pulses because it takes time to repeat the process of discharging and recharging the capacitor.

Besides being simple in equipment requirements, the CD pulse actually has another important advantage over the rectangular pulse. In 1987, a team of scientists from Stanford University conducted a comparative study in which mammalian cells were transfected with reporter genes using both short CD pulses with high field strength and long CD pulses of low field strength. It was found that the long CD pulse of low field strength gives a much higher transfection efficiency. Results of this work suggest that CD pulses with a large pulse width may be more efficient than narrow rectangular pulses in transfecting mammalian cells. Since then, the CD pulse has become a more popular choice for electroporation use.

More recently, a new type of waveform that utilizes an oscillating field has been developed. It is called a *DC-shifted radio-frequency (RF) pulse*. This RF pulse is found to have several advantages. First, this waveform is more effective in electroporating (or electrofusing) cells of heterogeneous size. As indicated in Eq. (3), the induced membrane potential is proportional to the radius of the cell. Thus, with a given applied electric field, the induced membrane potential will vary depending on the cell size. This can lead to a situation in which large cells may have too high a V_m and suffer excessive damage, while small cells may have too low a V_m such that their membranes do not breakdown. This problem can be solved using the RF pulses. Under an oscillating field, V_m is given by the following equation:

$$V_m = \frac{3Er\cos\theta}{2[1 + (\omega\tau_c)^2]^{1/2}} \qquad (4)$$

where ω is the angular frequency of the applied electric field; τ_m and other symbols have been previously defined. At a reasonably high frequency, V_m is almost inversely proportional to τ_c, which is in turn roughly proportional to the cell radius, r. Therefore, under an oscillating field, V_m is not very sensitive to r. As a result, both large and small cells will have a similar V_m under the same field and will both be efficiently electroporated without excessive cell damage.

Secondly, the RF pulse is more effective in inducing membrane breakdown. The oscillating field not only can cause a compression in the cell membrane, as the DC field can, but it can also drive the charged membrane lipids and proteins to undergo an oscillating motion. This motion in turn will create structural fatigue in the membrane and make it more susceptible to electrical breakdown.

Starting from 1990, we have demonstrated in a series of experiments in mammalian cells (including CV-1 cells, COS-M6 cells, and human red blood cells) that the RF waveform was able to provide a significantly higher efficiency in electroporation and electrofusion than the rectangular pulse or the CD pulse. Recently, another study was conducted to compare the RF electroporation with the conventional electroporation method. It was reported that the RF pulses were far more efficient in transfecting the *GFP* gene into a human embryonic kidney cell line.

2.2 Basic Procedures of Electroporation and Electrofusion

The equipment required for electroporating cells is relatively simple, mainly consisting of an electrical pulse generator and a cell chamber (Fig. 5). The major function of the pulse generator is to provide a high-voltage pulse with a large current output. This is necessary because the cell sample may have a very low resistance. The sample chamber not only contains the cell sample but also provides a pair of electrodes for applying the electric field. The electrodes are usually two

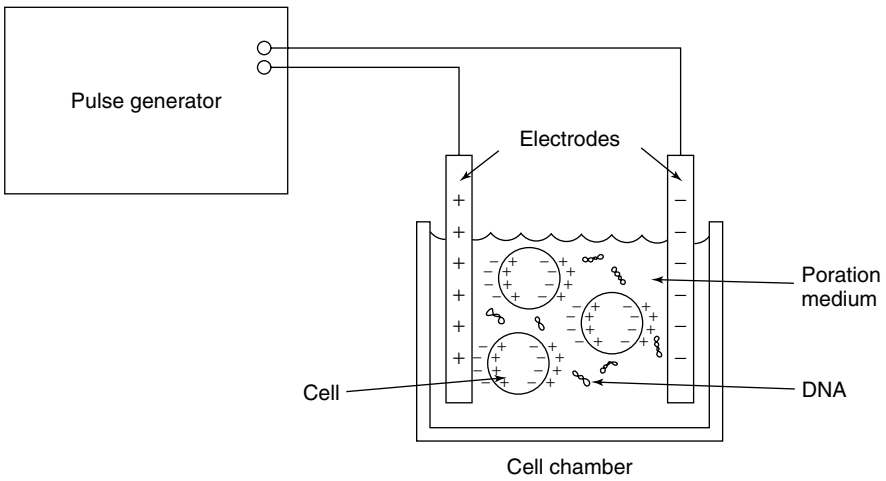

Fig. 5 A schematic diagram showing the basic device required for electroporation. Here, exogenous genes are introduced into cells by applying a pulsed electric field.

parallel metal plates made of platinum, stainless steel, or aluminum, with a typical distance of 0.1 to 0.4 cm.

The procedure of electroporation is also very simple. Suppose one wants to use electroporation to introduce certain recombinant DNA into a cultured cell line. The basic procedures are as follows:

1. When the cells are growing in the mid-log phase, harvest them using the standard cell-detach treatment.
2. Wash the cells at least once with a poration medium (PM) and resuspend them in PM. The composition of PM varies greatly between studies; it is basically an isotonic buffer with the majority of salt replaced by nonelectrolytes, such as sucrose or mannitol. DNA can be added to the cell sample at this time.
3. Load the cell sample into the chamber.
4. Apply the electrical pulse (or pulses) to the sample.
5. Transfer the cells from the sample chamber into the culture plate (or flask) and culture them in their normal conditions.
6. After the cells have been cultured for a sufficient length of time, they can be assayed for expression of the transfected gene or can be put under a selection process.

The procedures of electrofusion are similar to those of electroporation, except that cells must be placed in contact with their fusion partners before applying the intense electric field. Depending on the objective of the fusion, cells can be brought together using various methods, including mechanical, chemical, or electrical means. (See Section 1.3). The buffer used in electrofusion [called *fusion medium* (*FM*)] is also similar to the PM used in electroporation, except that FM must contain very little salt. This is particularly important when electrophoresis is used to bring cells together. The conductivity of the FM must be kept low to avoid generating excessive current in the cell sample.

2.3 *In situ* Electroporation of Attached Cultured Cells

In biomedical research, there is often a need to introduce exogenous molecules other than DNA (such as drugs, enzymes, antibodies, inhibitors, etc.) into living cells. The common method to achieve this aim is microinjection using a glass pipette. This method, however, is technically rather complicated. We have developed a unique method called *in situ electroporation*. Unlike the conventional electroporation method, which works mainly on suspended cells, this method allows us to introduce exogenous molecules into cultured cells in their attached state. This method does not require special sample preparation; cells can be grown on glass coverslips, just like those used for conventional microinjection. A special chamber was made in which an array of parallel Pt wires (with a constant gap) can be laid on top of the coverslip, so that a pulsed electric field can be passed across the cultured cells. (See Fig. 6). Using fluorescent-labeled molecular probes and reporter genes, it was demonstrated that this electroinjection method was highly efficient for a variety of cultured cells, including COS-M6, CV-1, 3T6, and C3H cells. This method is particularly useful for loading Ca^{2+} indicators (e.g. Calcium Green conjugated with dextran) for physiological studies. A fluorescent dye, such a rhodamine-dextran, can be coinjected as a marker. Recently, we have used this *in situ* electroporation method to inject cell-impermeable

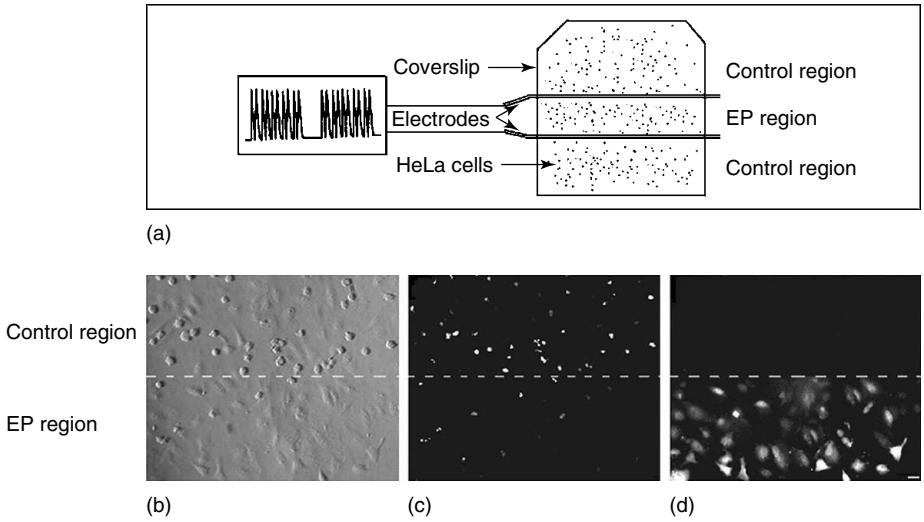

Fig. 6 (a) Schematic diagram showing the basic apparatus of *in situ* electroporation. Only cells between the two electrodes were electroporated and loaded with BAPTA. (b) DIC (differential interference contrast) image of cells at 5 h after UV treatment. Only cells undergoing apoptosis would round up. The dotted line shows the boundary between the EP and control regions. (c) Fluorescence image of nuclei (stained with Hoechst 33342) in the same field. Only apoptotic cells contained condensed chromatin, which appeared as bright spots under this magnification. (d) Fluorescence image of cells in the same field observed with a rhodamine filter, showing that only cells in the EP region were loaded with rhodamine-dextran and BAPTA. Bar, 20 μm.

calcium signal blockers, including BAPTA 1,2-bis-(*o*-aminophenoxy)-ethane-*N*,*N*,*N*′,*N*′-tetra-acetic acid and heparin, into attached HeLa cells for studying the effects of calcium signaling in UV-induced apoptosis. Other groups have also successfully used a different design of *in situ* electroporation to study cell signaling.

This *in situ* electroporation technique has several advantages. First, the experimental procedure was simple. There was no need to trypsinize the cultured cells and wait for the cells to reattach. Second, cell viability was improved owing to the abolishment of the trypsinizing procedure. Third, the gene transfer efficiency was found to be higher using the *in situ* electroporation method in comparison with the conventional electroporation method.

2.4 Factors Affecting the Efficiency of Electroporation and Electrofusion

There are many factors that can affect the efficiency of electroporation. The major ones include the following:

1. *Field strength*. This is probably the most important factor that can affect the efficiency of electroporation and cell viability. In order to electroporate cells, the induced membrane potential (V_m) must be large enough to approach the threshold potential, V_{th}. As indicated in Eq. (3), V_m is directly proportional to the applied field. If the applied electric field is too low, V_m will be much smaller than the threshold potential, and electrical breakdown of the cell

membrane will not occur. Under this situation, cells will not be properly electroporated or will fail to fuse. On the other hand, if the applied field strength is too high, V_m will be much greater than the threshold potential and will lead to irreversible membrane breakdown. The membrane will fail to reseal and the cells will no longer be viable. Thus, selecting a proper field strength is a critical step in both electroporation and electrofusion experiments.

As can be seen in Eq. (3), to generate a fixed V_m, the field strength required is inversely proportional to the radius of the cell. Thus, the field strength used to porate small cells, such as the *Escherichia coli* bacteria, is very high, typically on the order of 10 kV cm^{-1}. For larger animal cells, such as mammalian cultured cells, the applied field strength is typically about 1 kV cm^{-1}.

2. *Pulse width*. The second most important parameter is the pulse width, τ. When τ is too short, there will not be enough time for the membrane to develop an electrical breakdown. Too long a τ, however, will cause excessive damage to the membrane and the cell will not survive. When the rectangular pulse is used, the typical pulse width is less than 1/10th of a millisecond. For CD pulse or RF pulse, the pulse width may be significantly longer, on the order of milliseconds.

   The parameters of field strength and pulse width are found to complement each other. For a given cell type, the optimal value of E will shift upward when the pulse width is reduced.
3. *Number of pulses*. For some cells, a single pulse is sufficient for effective induction of electroporation or electrofusion. In most cell types, however, application of multiple pulses can greatly improve the efficiency of gene transfer.
4. *Growth condition of the cells*. To achieve high efficiency of gene transfer, cells must be harvested during the active growth phase prior to electroporation. If the cultured cells are grown for too long, the transfection efficiency will usually be low. It is recommended to replate the cells one or two days prior to electroporation.
5. *Other factors*. There are other relevant and influential factors, including temperature and the presence of divalent ions in the cell culture medium. For example, the concentration of Mg^{2+} may be critical to the efficiency of electroporation in some cell types. In some studies, it is recommended to add carrier DNA to enhance the efficiency of gene uptake during the electroporation process.

Most of the factors affecting the efficiency of electroporation can also affect the efficiency of electrofusion. There are also other factors that are uniquely important to electrofusion. For example, the alignment of cells can greatly influence fusion efficiency. To fuse cells, one must first bring the cells together before applying the high-intensity pulse. As discussed in Section 1.3, there are different methods of bringing cells together. Among them, the most elegant one is to use a low-amplitude oscillating field, which can induce cells to form a pearl chain by the process of dielectrophoresis. The optimal frequency and amplitude of the applied dielectrophoretic field for pearl chain formation depends on the diameter and the surface-charge properties of each individual cell. Thus, in order to maximize the efficiency of electrofusion, one needs to optimize the pearl chain formation process.

It has been suggested in some studies that certain chemical treatments of the cell surface can considerably increase electrofusion efficiency. For example, it was reported that pretreating red blood cells with pronase can greatly enhance the efficiency of electrofusion. Such an enhancement may be the result of removing some of the glycoproteins at the cell surface and thus allowing the neighboring cells to be closer to each other.

Another factor that can affect fusion efficiency is the osmolarity of the fusion medium. The cell membrane can be expanded using a partial osmotic shock to increase cell volume. Recently, this technique has been applied in the generation of human hybridomas. In this work, cells were treated with a hypoosmotic medium before the intense electric field was applied. It was reported that, with this treatment, the efficiency of electrofusion was greatly enhanced.

In our experience, the waveform of the electric pulse can also significantly affect fusion efficiency. We found that, by using a train of RF pulses, the electrofusion efficiency can be greatly increased as compared to protocols using rectangular pulses.

3 Applications

3.1 Applications of Electroporation in Gene Transfer

The most important application of electroporation is to introduce recombinant DNA into biological cells. Electroporation has been used for introducing genes into many different cell types, both eukaryotic and prokaryotic, including animal cells, plant cells, unicellular organisms such as algae or yeast, parasites, and bacteria. In fact, electroporation is now the method of choice for introducing genes into *E. coli*; the resulting transfection efficiency can be as high as 10^9 colonies per μg of DNA, which is almost thousandfold higher than that normally obtained by conventional methods.

Electroporation can be used for both transient and stable gene transfection in mammalian cells. In 1982, it was first demonstrated by T.K. Wong and E. Neumann that, using electrical pulses, a plasmid DNA containing the simplex virus thymidine kinase (*TK*) gene was successfully introduced into mouse L cells deficient of the *TK* gene. Stable transformants were obtained in this experiment. Later, electroporation was applied to transfect myeloma cells and a neuronal cell line. Within a few years, electroporation was used to introduce exogenous DNA into a variety of cells, including lymphocytes, neuronal cells, fibroblasts, endocrine cells, primary animal cultures, hepatoma cells, hematopoietic stem cells, and so on.

Today, electroporation is widely used in many studies of molecular biology for introducing genes into all sorts of cell types and for a wide variety of purposes. One common application of electroporation-mediated gene transfer is the study of gene regulation. Usually, a reporter gene is inserted into a plasmid vector with specific transcription promoter and enhancer sequences. By comparing the efficiency of gene expression under various conditions, such as the availability of certain transcriptional factors, one can gain knowledge about how the gene of interest is regulated. Alternatively, one may mutate the upstream sequences of a certain gene, fuse it with the reporter gene, and then introduce it into cells by electroporation.

By comparing the resulting level of gene expression under various mutation conditions, one can identify the major promoter or enhancer sequences.

In addition, functional genes can be introduced into mammalian cells by stable transfection using electroporation. This can be done by coinserting a drug-resistance gene with the gene of interest into the cell genome and then subjecting the cell to a selection media containing the specific drug (such as G418). Using this method, a large number of different types of DNA have been transfected into a variety of mammalian cells. For example, the complete human immunoglobulin κ (*Ig*κ) gene was stably transfected into mouse L cells and mouse pre-B-cells by electroporation. Northern blot analysis of RNA indicated that the expression of the *Ig*κ gene is highly tissue-specific.

Not only can electroporation be used for introducing genes into cells to produce stably transfected cell lines but also a similar method can be used to introduce genes directly into eggs or stem cells for the generation of transgenic animals. For example, it has been reported that transgenic zebrafish can be produced using electroporation. Electroporation has also been used to introduce genes into plant cells. For example, using electroporation, genes have been successfully introduced into protoplasts of a number of plants, including carrot, maize, and tobacco leaf mesophyll cells. In addition, this technique can be applied to make transgenic plants. It has been reported that electroporation can be used for the generation of transgenic cereal plants such as rice and sorghum.

In comparison with other methods of gene transfer, such as those using calcium phosphate or retroviruses, electroporation has several distinctive advantages. First, it is a simple method. The procedure takes only minutes, and there is no need for prior treatment of the DNA to be inserted. Secondly, electroporation is efficient. In comparison with the chemical methods using calcium phosphate or DEAE dextran, electroporation usually offers much higher transfection efficiency. Thirdly, since electroporation is a physical method, it is widely applicable to many cell types. Unlike the chemical method or the virus vector, electroporation is less dependent on the surface properties of the cell membrane, and hence, electroporation can be used to introduce genes into a very wide spectrum of different cell types. Finally, electroporation is a relatively ''clean'' method because it involves little chemical or biological hazard compared with the chemical and retroviral methods.

3.2 Electroinjection of Other Molecules

Besides genes, electroporation can be applied to introduce many other types of molecules into living cells. In fact, the early usage of electroporation was to introduce ions, such as calcium, and small molecules, such as ethyleneglycol-bis-(β-aminoethyl)-*N*,*N*,*N*′,*N*′-tetra-acetic acid (EGTA) and ATP, into cells. Lately, electroporation has also been used to introduce fluorescent-labeled dextran and molecular probes such as Calcium Green-1. Electroporation can also be used to introduce large molecules such as antibodies into cells. For example, using electroporation, monoclonal antibodies have been introduced into HeLa cells and murine lymphoma cells. Furthermore, electroporation has been used for the introduction of a number of active biological compounds, including restriction enzymes, Epstein–Barr virus episomal replicons, substrates of enzymes,

and drugs that block certain signal transduction pathways.

One particular interesting example of using the electroporation technique for studying cell signaling is our recent investigation of the involvement of Ca^{2+} signals in UV-induced programmed cell death. In the last few years, several groups had reported that application of a membrane-permeant form of a Ca^{2+} chelator (BAPTA/AM) failed to prevent cells from entering apoptosis. These findings raised a serious question on whether the Ca^{2+} signal is truly involved in regulating the progression of programmed cell death. To resolve this question, we examined the differential effects of three different Ca^{2+} signal blockers (membrane-permeant BAPTA/AM, membrane-impermeant BAPTA, and heparin) on UV-induced apoptosis in HeLa cells. We found that although BAPTA/AM could not inhibit cell death, the membrane-impermeant form of BAPTA, loaded into the cytosol by electroporation, clearly protected cells from entering apoptosis (Fig. 6). Furthermore, when we injected heparin to block Ca^{2+} release from the endoplasmic reticulum (ER) to the cytosol, apoptosis was greatly suppressed. These findings strongly suggest that elevation of cytosolic Ca^{2+} is part of the signal that drives the progression of apoptosis. The negative result of BAPTA/AM is probably due to its dual effect on subcellular Ca^{2+} distribution; besides suppressing the Ca^{2+} elevation in cytosol, BAPTA/AM can also enter into the ER to reduce the free Ca^{2+} level there. The depletion of Ca^{2+} in ER is believed to stimulate apoptosis and thus would counterbalance the protective effect of BAPTA/AM in suppressing the cytosolic Ca^{2+} elevation.

3.3 Study of the Mechanism of Membrane and Cell Fusion

Electrofusion has been used for studying the mechanism of membrane fusion. Most of these works were done using either a model membrane such as lipid vesicles or cells with simplified membrane structure, such as red blood cells or red cell ghosts. More recently, electrofusion has been used for the study of cytoplasmic fusion. Cytoplasmic fusion is more difficult to study than membrane fusion because the process involved takes a much longer time. The fusing cells must be maintained in their normal physiological state for a long period for observation. Such a requirement excludes some of the common fusogens, like polyethylene glycol (PEG) or a virus, that may have toxic effects. Furthermore, in order to study the dynamic changes in cytoplasmic structures, cell fusion must be induced by a treatment that requires very little time, and the fusion process must be relatively synchronized.

These requirements can be satisfied by using the electrofusion technique. The fusion event can be induced by applying a short pulse of electric field; the fusion efficiency is very high, about 70%. The fusion of all cells exposed to the same electrical pulse would occur almost in synchrony. Because of these advantages, the electrofusion method has been used to study the reorganization of various cytoplasmic components, including cytoskeletons and organelles, during the fusion of mammalian cells.

3.4 Production of Hybridomas and Antibodies

An important application of electrofusion is to make hybridomas for the production

of monoclonal antibodies. For example, mouse myeloma cells can be fused with mouse lymphocytes and then selected for clones producing a specific antibody. Traditional methods using a chemical fusogen, such as PEG, are not as efficient as electrofusion. Several comparative studies have shown that electric field–induced cell fusion can be 1000-fold more efficient than fusion events initiated by chemical means. Lately, there has been a strong interest in making human hybridomas for producing human antibodies, which would obviously be much more useful than animal antibodies for medical purposes. The production of human hybridomas is particularly difficult because, with the conventional fusion methods, the fusion between antibody-producing cells and human plasma cells usually has very low yield. Recently, by using the electrofusion technique, several groups were able to develop new protocols to produce human hybridomas successfully.

4 Perspectives

4.1 Future Applications of Electroporation in Molecular Biology

One of the most important applications of electroporation as a gene transfer technique in molecular biology is gene targeting. At this time, it is difficult to use other methods of gene transfer to conduct homologous DNA recombination. For example, in the retroviral method, the inserted gene is flanked by long terminal repeat (LTR) sequences, which have a tendency to insert the recombinant gene into random sites on the genome. This will defeat the purpose of homologous recombination. Chemical methods, such as those using calcium phosphate, have the disadvantage of inserting multiple copies of the recombinant gene into the genome; the number of copies is uncontrollable. These problems can be avoided by using electroporation as the gene transfer method. With this method, one can control the copy number of recombinant DNA to be inserted into the genome. Also, by linking with proper flanking sequences, the gene introduced by electroporation can be directed to integrate into the proper site of the genome. Hence, electroporation has become a very important tool for gene targeting work.

Another advantage of the electroporation method is that it is less cell-type dependent. Both the chemical methods and the retrovirus method depend on the surface properties of the target cells, and thus, certain cell types are resistant to transfection mediated by chemicals or viruses. It happens that some of the cell types that are highly important for gene therapy, such as lymphocytes and stem cells, are generally resistant to the common retrovirus vectors. Since electroporation is a physical method, it is not particularly sensitive to the composition of the membrane proteins, and, thus, is less cell-type dependent. So, in principle, once the electroporation method is properly optimized, it can be applied for introducing genes into most target cells.

4.2 Electroporation as an Important Tool for Studying Cell Signaling

At present, electroporation has been mainly used in molecular biology. With time, this technique will have the potential to become an important tool in the study of cell biology. Electroporation can be used as

a massive microinjection technique. Currently, microinjection is done by means of a glass pipette, which is tedious, requiring expensive equipment and extensive training. It is also difficult to inject a large number of cells at one time. With electroporation, one can inject thousands or even millions of cells, within a few minutes. Thus, electroporation can become a very efficient injection method.

One of the major uses of electroporation is to introduce molecular probes, such as ion indicators (e.g. for Ca^{2+} or H^{+}) or cell-labeling dyes. At present, most of the calcium indicators, such as fura-2 or fluo-3, are introduced into the cell either by direct injection or by modifying the indicators into triacetoxymethyl ester (AM) forms that can permeate to the cell membrane. However, by the latter methods, the amount of molecules introduced is difficult to control. Certain portions of the AM-form indicator could also be taken up by the intracellular organelles, thus making it more difficult to interpret the experimental results. These problems can be avoided by using electroporation to introduce non-AM-form indicators. Electroporation has been demonstrated to be efficient in injecting several different molecular probes into a wide variety of cells, including animal, plant, and unicellular cells. The amount of molecules injected usually can be controlled by varying the electroporation conditions.

In the future, the most potentially useful application of electroporation is probably the introduction of various substances into cells to study the processes of signal transduction. For example, one can introduce kinases or phosphatases, their substrates, activators, or inhibitors into cells to study a hypothetical signal transduction pathway. It is well known that many of the cell functions are regulated by the phosphorylation and dephosphorylation of certain proteins. The signal pathway usually involves multiple components and a cascade of kinase/phosphatase activities. It is very difficult to study such a pathway. With the electroporation technique, one can introduce reagents into the living cell to specifically inhibit or activate a selected step of the signaling process and then observe the resultant cellular responses. In this way, one can examine the functional role of a specific signaling molecule and can eventually gain a better overall understanding of the entire signal transduction pathway under study.

Similarly, one can use electroporation to introduce many other factors that are important for biological regulations, such as transcription factors, gene products of oncogene or tumor suppressor genes, small G proteins, intracellular receptors of hormones or other signaling molecules, and so on. The ability to introduce these factors into a large number of living cells will open up new opportunities for examining the molecular mechanism of many important cellular functions.

4.3 Use of Electroporation for Gene Therapy

The electroporation method can be applied in many areas of biomedical science. One important use of this method is for gene therapy. Since the target cells in this case are normally obtained from the patient, the quantity of cells available for gene insertion is usually limited. Also, no side effects can be tolerated in such a transfer procedure. At present, most gene therapy studies use virus vectors to insert the recombinant gene. This method creates a high risk for patients because the virus could be reactivated

under certain circumstances (such as infecting by a wild-type virus of similar strain). Being a physical method, the electroporation technique does not have such a risk. By improving the efficiency of gene transfer, electroporation can become the method of choice for gene therapy. It is particularly useful in the explant approach. For example, electroporation can be used to introduce therapeutic genes into bone marrow cells isolated from a patient. After the introduced genes are expressed successfully, cells can be retransplanted into the same patient.

In recent years, a new use of electroporation for medical purpose has been developed; it is the *in vivo* application of electrical pulses for the delivery of drugs or DNA into cells or tissues. *In vivo* electropermeabilization can be achieved by using either invasive electrodes (e.g. needles) or surface electrodes (metal plates). Such electrodes could be used to permeabilize cells in the skin or the skeletal muscle. One important application of this *in vivo* electroporation method is for electrochemotherapy, in which a cell nonpermeant antitumor drug (such as bleomycin) can be introduced directly into the patient's cells in a local region. In the future, besides chemotherapy drugs, one can also use this method to introduce active oligonucleotides directed to specific genes of the patient. A second important application of *in vivo* electroporation is to introduce therapeutic genes directly into the patient's cells. Using electrical pulses of different waveforms, several groups had reported various degrees of success in transferring plasmids into skin cells, liver tissue, skeletal muscle, and tumors during the last several years. Although there are still many technical problems to be overcome, the *in vivo* electroporation technique has already been recognized as an important future tool for gene therapy.

Keywords

Adaptor
A small molecule consisting only of binding domains (e.g. SH2 domains, which bind phosphotyrosine, and SH3 domains, which bind polyproline helices) and used to associate proteins.

G-protein
A GTP-binding protein with intrinsic GTPase activity; it acts as a molecular switch with a built-in timer; it is ''on'' when bound to GTP and ''off'' when bound to GDP.

Hormone
A chemical, nonnutrient, intercellular messenger that is effective at very low concentrations.

Hormone Response Element (HRE)
A DNA sequence recognized by a transcription factor that is primarily regulated by hormones.

Oncogene
A gene that usually encodes a component of the growth factor pathway and that has undergone a mutation resulting in constitutive activity and tumor formation.

Endocrinology is the study of hormones, chemicals that cells use to communicate with each other. Traditionally, endocrinology was studied at the organismal level: the effects of hormones on tissue or animal growth, reproduction, or metabolism. Molecular endocrinology seeks to determine the molecular mechanisms for these gross effects: the actions of hormones, direct or through mediators, on enzymes, transport processes, the cytoskeleton, and transcription factors. Such information is vital to understanding how complex metazoans coordinate cellular functions. In addition, this knowledge can be useful in the evaluation and treatment of various endocrine diseases that have genetic bases. Furthermore, many tumors arise when the genes for various growth-promoting hormones or for components of their signaling pathway undergo mutations that render them constitutively active.

1 Introduction

Multicellular organisms have two major coordinating systems: the nervous and the endocrine systems. Both utilize chemical messengers: in the endocrine system, these molecules are called *hormones* and are usually secreted into the circulatory system for general distribution. In the nervous system, the molecules are called *neurotransmitters* and are released into synapses for more precise effects. The distinction is not always this clear; many of the chemicals used by each system and their mechanisms of action are identical. In addition, some hormones are made and act locally in a very defined area, while some neurotransmitters can leak out into the general circulation. Thus, there is a general tendency to consider all chemical messengers as a single functional group.

2 Hormones

Structurally, hormones are extremely diverse; nearly every organic group is represented. Proteins and peptides are the largest group. In addition, there are hormones that are derivatives of amino acids, sterols, fatty acids, phospholipids, nucleotides, and carbohydrates. There are even several gaseous hormones, such as ethylene and nitric oxide.

However, one property divides all hormones into two major groups and will determine their mechanisms of action: water solubility. Hydrophobic ligands have no problem crossing the plasma membrane; as such, these hormones have a direct mechanism of action. In particular, they migrate to the nucleus where they interact with transcription factors. Since their mechanism is primarily genomic, their effects tend to be delayed and long term; they are often involved in developmental processes and long-term adaptation. Hydrophilic hormones cannot cross the plasma membrane and must interact with binding proteins, the receptors. Since these receptors are integral membrane proteins, they must generate another signal on the cytosolic side; if the hormone is the primary messenger, then this subsequent factor becomes a second messenger. These latter messengers often activate kinases that can have acute effects on metabolism and cell structure or phosphorylate transcription factors for more long-term effects.

3 Receptors

3.1 Nuclear Receptors

As noted in Section 2, the receptors for lipophilic hormones are ligand-regulated transcription factors. These receptors are all homologous: the amino terminus possesses a transcription activation domain (TAD), and the center has a DNA binding region. The carboxy terminus binds the hormone, heat shock proteins (hsps), and immunophilins; it also contains a dimerization domain and a second TAD. The hsps are necessary to maintain the receptors in a conformation required for ligand binding, and the immunophilins may be involved in nuclear transport; once the hormone binds, these proteins dissociate (Fig. 1). Ligand binding also induces receptor dimerization, phosphorylation, nuclear translocation (although some receptors are constitutively located in the nucleus), DNA binding, and transcription activation. After

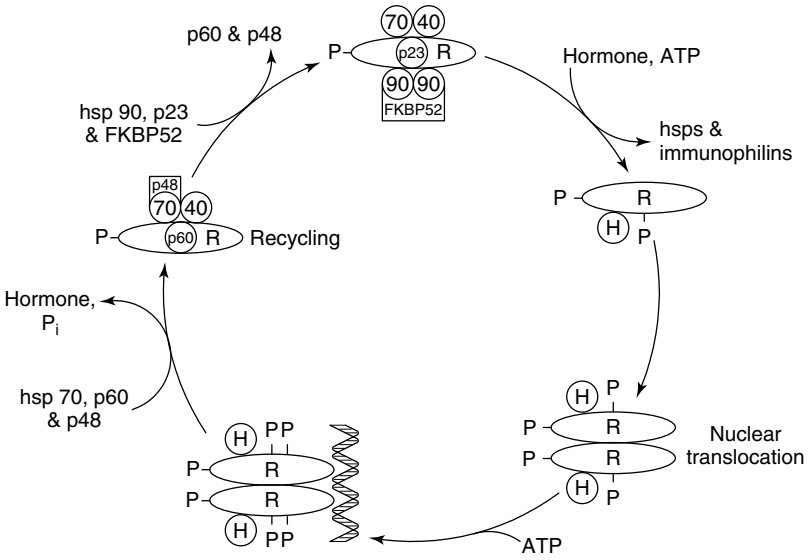

Fig. 1 Activation and recycling of a nuclear receptor: 40, 70, 90, p23, p48, p60, heat shock proteins; FKBP52, an immunophilin; H, hormone; P, phosphorylation site; R, receptor.

the hormone dissociates, the receptor is dephosphorylated and recycled.

The nuclear receptors can be divided into three families on the basis of their structures and the DNA sequences to which they bind. The glucocorticoid family is the most recently evolved group and contains the cortisol, aldosterone, androgen, and progesterone receptors. The members of this family are basically homodimers, require hsp 90, and bind inverted repeats of the hormone response element (HRE) TGTTCT. The thyroid hormone family is the oldest and most diverse group and includes receptors for the thyroid hormone, vitamins A and D, ecdysone, and arachidonic acid. They are most active as heterodimers, do not require hsp 90, and can bind either direct or inverted repeats of TGACC. The estrogen family contains only the estrogen receptor and a few related receptors whose ligands are still unidentified. Its properties lie between the two other groups: it binds the thyroid hormone HRE, but only as inverted repeats; in addition, it forms homodimers and requires hsp 90 like the glucocorticoid family.

3.2 Membrane Receptors

Membrane receptors are considerably more diverse. Four basic superfamilies are recognized: the enzyme-linked receptors, cytokine receptors, G-protein coupled receptors, and ion channel receptors (Fig. 2). The enzyme-linked are the simplest: the basic structure consists of a single protein that traverses the plasmalemma once via an α-helix. The amino-terminal extracellular domain binds the hormone, while the carboxy-terminal cytosolic domain possesses a catalytic site. Ligand binding induces oligomerization and enzyme activation. Three types of enzymatic activity have been identified:

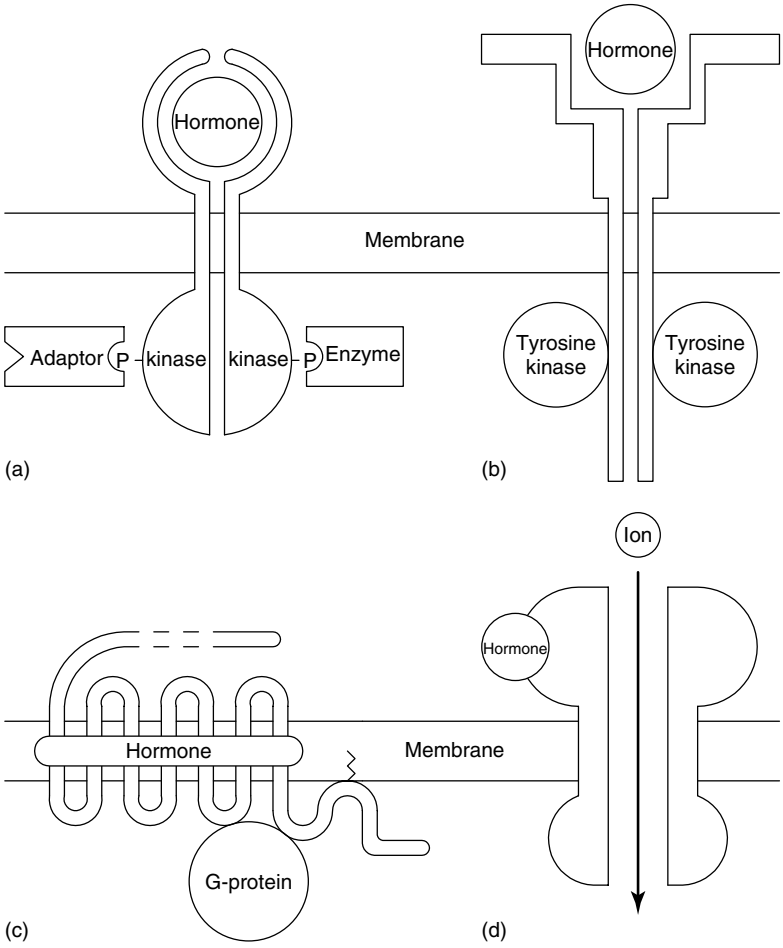

Fig. 2 Schematic representation of several classes of membrane receptors: (a) receptor tyrosine kinase, (b) cytokine receptor, (c) G-protein coupled receptor, and (d) ligand-gated ion channel.

first, the tyrosine kinases are represented by six families (the epidermal growth factor, insulin, platelet-derived growth factor, nerve growth factor, ephrin, and collagen groups); the serine–threonine kinases are found only in the transforming growth factor β family; and the guanylate cyclases generate cyclic GMP (cGMP) in response to atrial natriuretic peptides.

In the case of the receptor tyrosine kinases (RTKs), they serve as the major substrates themselves. Phosphorylated tyrosines are recognized by SH2 domains that are found in many enzymes and adaptors; these latter proteins will bind the autophosphorylated receptors and then mediate many of the biological activities of RTKs (see Section 4).

The cytokine receptors have the same structure as the enzyme-linked binding proteins except that there is no recognizable catalytic site in the cytosolic domain.

The extracellular region is composed of two modified units first identified in fibronectin, a matrix protein. In the class 1 receptors, these units form two seven-stranded β sheets that join at right angles to create a ligand-binding pocket (Fig. 2b). This core may be further embellished by immunoglobulin loops and/or additional fibronectin domains. The class 2 receptors form repeats of five-stranded β sheets that extend over the hormone like fingers.

In the cytosolic juxtamembrane region of the cytokine receptors is a conserved proline-rich region that constitutively binds soluble tyrosine kinases. Like RTKs, these kinases are activated by receptor aggregation induced by ligand binding. As such, the cytokine receptors can be considered RTKs whose catalytic site is located on a separate subunit.

The next superfamily has many names: G-protein coupled receptors (GPCR), seven transmembrane segment receptors, heptahelical receptors, and serpentine receptors. This chapter will use the first term because of its wide usage. The GPCRs are probably the oldest and most diverse of the membrane receptors and mediate both sensory and endocrine transduction. The protein traverses the plasma membrane seven times; several of these transmembrane α helices have conserved prolines that kink the helices, resulting in the formation of a ligand-binding pocket (Fig. 2c). As such, most of the hormones using these receptors are small: for example, the catecholamines, histamines, prostaglandins, and so on. Receptors with larger ligands often have extended amino termini to aid in hormone binding. Several of the intracellular loops bind and activate G-proteins (see Section 4.1), especially the third loop and the juxtamembrane portion of the carboxy terminus. The latter also forms a loop because its midsection is held to the plasma membrane by a palmitic acid that is covalently bound to a conserved cysteine in the carboxy terminus.

The last superfamily includes the ligand-gated ion channels that comprise three families. The cysteine-loop family is a pentamer of homologous subunits; each subunit contributes an α-helix toward forming the wall of the channel. This helix is kinked with the elbow directed toward the center of the channel; furthermore, the bend is populated by hydrophobic amino acids that obstruct the channel in the closed state. Hormone binding causes the helix to rotate; the hydrophobic side chains are moved laterally, and the channel opens. Acetylcholine activates sodium channels; glycine and γ-aminoisobutyric acid, chloride channels; and serotonin, calcium channels.

The voltage-gated channels are the prototype for the P (or H5) family. They are homotetramers; each subunit has six transmembrane helices. The pore is formed by a loop between the last two helices. Two subfamilies from this group are regulated by second messengers: first, the cyclic nucleotide–gated channels are cation pores opened by cAMP or cGMP. The second family gates channels that release internal stores of calcium; they include the inositol 1,4,5-trisphosphate (IP_3) and the cyclic ADP–ribose receptors (see Section 4.2). The glutamate receptors are another subgroup of the P family. They have only three transmembrane helices, and the pore-lining loop is between the first two helices. They are calcium channels.

The structure of the last superfamily, the epithelial sodium channels, is still controversial. They include the P_{2X} purinergic receptor and the FMRF amide-gated channel.

4
Second Messengers

4.1
G-proteins and Cyclic Nucleotides

G-proteins are molecular switches: they are active when GTP is bound to them and inactive when GDP is bound. In addition, they have intrinsic, although weak, GTPase activity; as such, they eventually turn themselves off when they hydrolyze the bound GTP to GDP. In the active state, they can stimulate enzymes, ion channels, and affect the cytoskeleton and vesicular trafficking (Table 1).

For a hormone to "flip" this switch on, it must facilitate the exchange of GDP for GTP. For example, the conversion of Ras.GDP to Ras.GTP is accomplished by a Ras GNP exchange facilitator (RasGEF), which is under hormone regulation (Fig. 3). In fact, there are several different types of RasGEFs, each with its own mechanism of control. In neurons, one RasGEF (called RasGRF1) is directly activated by calcium and a calcium-binding protein, called *calmodulin* (see Section 4.2); on the other hand, phosphorylation by a cAMP-dependent protein kinase will inhibit this GNP exchange facilitator (GEF). Another GEF, CNrasGEF, directly binds cyclic nucleotides and is stimulated by them. A third RasGEF (called mammalian SOS) is activated indirectly: receptor or soluble tyrosine kinases either phosphorylate themselves or some docking protein. An adaptor (Grb2) binds to the phosphotyrosine via its SH2 domain; Grb2 also has an SH3 domain that binds polyproline helices. Such a helix is present in RasGEF so that a complex among a tyrosine phosphorylated protein, Grb2, and RasGEF is formed. This complex activates RasGEF, which then stimulates nucleotide exchange on Ras. Once formed, Ras.GTP binds to Raf, a serine–threonine kinase, and brings it to the plasmalemma where it is stimulated by a still unknown process. Finally, Raf initiates a protein kinase cascade that eventually

Tab. 1 Some G-protein families and their functions.

Group	*Members*	*Function*
Ras superfamily		
Ras	Ras	Mitogenesis
	Ral	Endocytosis, vesicular trafficking
	Rap	Cell adhesion
	Rad, Gem, Kir	Cytoskeletal organization, secretion, Rho kinase inhibition
Rho family	Rho, Rac, Cdc42	Cytoskeletal organization, NADPH oxidase activation
Rab family	Rab	Vesicular trafficking
Ran family	Ran	Chromosomal condensation, nucleocytoplasmic transport, microtubule assembly (spindle)
Arf family	Arf	Endoplasmic reticulum–Golgi vesicle interactions
G-protein trimer	G_s, G_i, G_q, G_{12}, G_{13}	Hormone signal transduction
Elongation factor	EF-Tu	Translation proofreading
Signal recognition particle	SRP54	Transfer of proteins across the endoplasmic reticulum
Dynamin	Dynamin	Assembly of clathrin-coated vesicles vesicular neck constriction

activates mitogen-activated protein (MAP) kinase, a critical kinase in transcription regulation (see Section 5.2). Other small G-proteins can directly bind and stimulate protein kinases (Table 2): for example, Rho activation of protein kinase N (PKN) and Rho-associated, coiled-coil forming protein kinase (ROCK); or Rac activation of the p21-activated kinase (Pak).

The GTPase activity of small G-proteins is so weak that they require accessory proteins, the GTPase activating proteins or GAPs. This is another potential site for hormone input: RasGAP can be inhibited by phosphoinositide binding, thereby prolonging the activated state of Ras.GTP. Interestingly, RasGAP, in addition to terminating the Ras signal, may also mediate some of the effects of Ras prior to GTP hydrolysis. Other potential control points include the GDP dissociation inhibitor (GDI), which opposes the GEF, and the GTPase-inhibiting protein (GIP), which opposes the GAP.

The large G-proteins occur as heterotrimers: the α-subunit is the GTPase, while the $\beta\gamma$ dimer is involved with membrane localization and protein association. Although the GTPase activity of α is not as slow as that in the small

Tab. 2 Some multifunctional serine–threonine kinases involved with hormone action.

Kinase	*Abbreviation*	*Structure*	*Activator(s)*
Protein kinase A	PKA	Tetramer	cAMP
Protein kinase B	PKB	Dimer	$PI(3)P_n$
Protein kinase C	PKC	Monomer	Calcium and diacylglycerol
Protein kinase G	PKG	Homodimer	cGMP
Calmodulin-dependent protein kinase II	CaMKII	Dodecamer	Calmodulin
Rho-associated coiled-coil forming protein kinase	ROCK	Monomer	Rho, inhibited by Rad
p21-activated kinase	Pak	Monomer	Rac
Casein kinase 2	CK2	$\alpha\beta$ dimer	Polyamines and phosphorylation
Glycogen synthase kinase 3	GSK3	Monomer	Inhibited by PKB or PKC phosphorylation
Mitogen-activated protein kinase	MAPK	Monomer	Ras and PKC via a kinase cascade

G-proteins, it still has a GAP, called negative regulator of G-protein signaling (RGS). There are four large G-protein families: G_s stimulates adenylate cyclase, G_i inhibits adenylate cyclase, G_q stimulates phospholipase Cβ (PLCβ), and $G_{12/13}$ activates phospholipase ε, protein phosphatase (PP) 5, and a RhoGEF. These G-proteins also directly stimulate several soluble tyrosine kinases and ion channels. The hormone–receptor complex directly accelerates nucleotide exchange, resulting

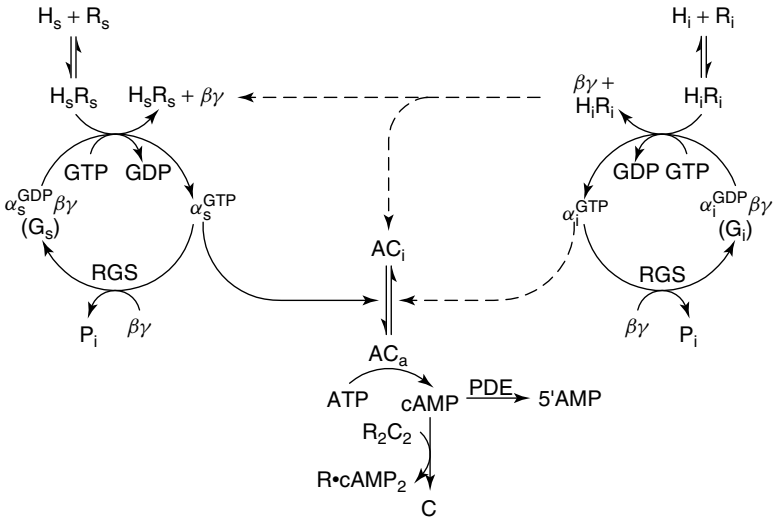

Fig. 4 Regulation of adenylate cyclase by several G-protein trimers. Inhibitory effects are depicted by dashed lines: H_iR_i, adenylate cyclase inhibiting hormone and its receptor; H_sR_s, adenylate cyclase stimulating hormone and its receptor; R_2C_2, PKA tetramer containing two regulatory (R) and two catalytic subunits (C); RGS, negative regulator of G-protein signaling.

in the activation of α_s and the dissociation of $\beta\gamma$ (Fig. 4). As long as GTP remains bound to α_s, adenylate cyclase will be stimulated. However, α_s will eventually hydrolyze GTP and reassociate with $\beta\gamma$. G_i represents a counterregulatory mechanism that operates in a parallel manner except that both α_i and $\beta\gamma$ participate in the inhibition of adenylate cyclase.

The ultimate output to this pathway is cAMP, which can activate several enzymes and ion channels; however, the major effector for cAMP is a serine–threonine kinase (protein kinase A or PKA). This tetramer has two catalytic subunits and two inhibitory subunits (Table 2). cAMP binds to the regulatory subunits and causes them to dissociate, thereby removing the inhibition.

cGMP is another cyclic nucleotide used as a mediator of hormone action; it may be generated by two different pathways. The first pathway, discussed in Section 3.2, involves a hormone that directly binds and activates a membrane-bound guanylate cyclase. cGMP may also be synthesized by a soluble cyclase; this enzyme is activated by nitric oxide whose synthesis is stimulated by hormones that elevate calcium (see Section 4.2). Like cAMP, cGMP stimulates both ion channels and a homologous kinase, protein kinase G or PKG. In this kinase, the regulatory and catalytic subunits are fused into a single protein.

4.2 Calcium, Calmodulin, and Phospholipids

Calcium is an abundant cation in extracellular fluids; in addition, it is concentrated within several cellular organelles, such as mitochondria and elements of the smooth endoplasmic reticulum. However, cytosolic levels are kept extremely low, because many cellular processes are dramatically affected by calcium. As such, hormones can regulate these cellular functions by controlling the cytoplasmic calcium concentrations. The most direct mechanism for elevating calcium would be for hormones to activate ligand-gated calcium channels, such as the glutamate receptor; by merely opening these channels, hormones would cause external calcium to flood the cytoplasm.

However, a major source of hormonally released calcium is internal (Fig. 5, middle). Briefly, hormones stimulate a PLC to hydrolyze a phospholipid (polyphosphoinositide) to diacylglycerol (DG) and the former head group (IP_3). There are several PLC groups distinguished by both their structure and their hormone regulation. PLCγ possesses two SH2 domains through which it binds to autophosphorylated RTKs; this association brings the enzyme into close proximity with its substrate and allows RTKs to phosphorylate and stimulate the PLCγ. On the other hand, PLCβ is allosterically activated by α_q or $\beta\gamma$; PLCδ, by calcium; and PLCε, by Ras, Rap, or G_{12}.

Once released, IP_3 diffuses through the cytosol to its receptor, a calcium channel on the endoplasmic reticulum. IP_3 binding opens the channel and allows the internally stored calcium to enter the cytoplasm. The DG remains in the plasma membrane where it stimulates a calcium-activated, phospholipid-dependent protein kinase, protein kinase C (PKC). Actually, there are three PKC groups that differ in their calcium and DG requirements: the conventional PKCs require both calcium and DG; the novel PKCs require only DG; and the atypical PKCs are activated by alternate second messengers, such as arachidonic acid. DG can also have other effects, including the activation of an acid sphingomyelinase and GEFs for Ras and Rap.

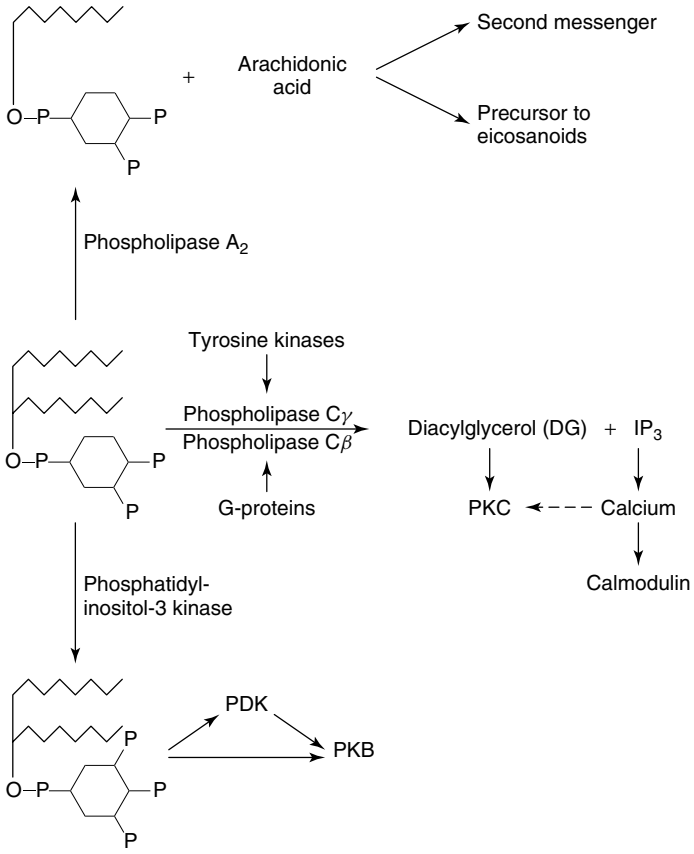

Fig. 5 Brief summary of several phospholipid pathways: IP_3, inositol 1,4,5-trisphosphate; PDK, phosphoinositide-dependent kinase; PKB, protein kinase B; PKC, protein kinase C.

Once elevated, calcium alone can directly affect many enzymes, the cytoskeleton, and other biological processes. However, it frequently acts through a calcium-binding protein, calmodulin (CaM). CaM is a small dumbbell-shaped peptide with the two globular ends separated by an α-helix. Calcium binding to the globular ends allows the groove found in each end to wrap around an α-helix in the target protein. The central α-helix of CaM helps determine binding selectively: it has an acidic and a hydrophobic end and is attracted to target proteins having an exposed α-helix with a basic and a lipophilic end. Such amphipathic helices often inhibit the proteins that possess them, and their masking by CaM prevents this autoinhibition. For example, the CaM-dependent protein kinase II, a general-purpose serine–threonine kinase, has a CaM binding site that blocks both the ATP binding and catalytic sites. In the presence of calcium, CaM binds to this site, prevents it from interfering with ATP and substrate binding, and activates the kinase. There are many other enzymes and channels that operate on the same principle.

Phospholipids may give rise to many other second messengers: for example, almost all growth factors stimulate a phosphatidylinositol-3 kinase, which generates a phospholipid that cannot be hydrolyzed by any known PLC. Rather, the intact molecule is a second messenger that activates several protein kinases, such as the phosphoinositide-dependent kinase (PDK) and protein kinase B (PKB); stimulation of the latter requires both the phospholipid and phosphorylation by PDK (Fig. 5, bottom). PKB is a major antiapoptotic signal.

Phospholipase A_2 can also generate signaling molecules, and it can be stimulated by hormones via MAP kinase phosphorylation and calcium. It liberates the fatty acid in the second position of phosphoglycerides; this is usually arachidonic acid. The free arachidonate may stimulate enzymes or other effectors, or it may be converted to prostaglandins or other eicosanoids (Fig. 5, top). These latter fatty acid derivatives are hormones in their own right: they are secreted, bind to specific membrane receptors, and stimulate various second messenger pathways. However, they usually act locally; such molecules are called *parahormones* and they may adjust a cell's response to other hormones or to local conditions. A lysophospholipid is what remains after the arachidonic acid has been removed, and it is also biologically active.

Finally, another membrane lipid, sphingomyelin, can be the source of several mediators of hormone action. Sphingomyelin is structurally similar to phosphatidylcholine except that it has a serine rather than a glycerol backbone. Acid sphingomyelinase is activated by DG, while the neutral sphingomyelinase is stimulated by an adaptor to the tumor necrosis factor receptor. These enzymes generate ceramide, which can then be converted to sphingosine-1-phosphate by phosphorylation. The former mediates apoptosis, while the latter stimulates proliferation.

4.3 Miscellaneous Mediators

Several other second messenger systems have been postulated, but they have not yet been sufficiently explored to determine their physiological relevance to hormone action. Polyamines are small basic molecules that are required for transcription and translation. They can also activate a protein kinase, casein kinase 2. Hormonal regulation is achieved by the induction of the enzymes for polyamine synthesis; hormones can also stimulate polyamine transport into cells from the surrounding medium.

The hydrogen ion concentration represents another potential mediator of hormone action. All mitogenic stimulation is accompanied by a slight rise in cellular pH. This alkanization has been shown to be necessary, but not sufficient, for subsequent cell division. It is not clear what the output for this signal is; although many cellular reactions are pH sensitive, pH optima are rarely so sharp that a few tenths of a pH unit would make a significant difference in overall activity. Growth factors raise the pH by activating the sodium–hydrogen exchanger 1 (NHE1) by PKC phosphorylation, G-proteins, or calcium–calmodulin binding to an autoinhibitory site.

5 Biological Effects

5.1 Nongenomic

There are two major mechanisms by which hormones can affect cellular processes:

allosterism and phosphorylation. For example, G-proteins can directly bind and alter the activity of both enzymes (e.g. adenylate cyclase, phospholipases, and several kinases) and transporters (e.g. ion and glucose channels and the NHE1). Similarly, cyclic nucleotides can stimulate nucleotide-gated channels and protein kinases. Lipophilic hormones, which have direct access to the cellular interior, have also been shown to bind directly several enzymes, but the physiological relevance of these observations is still controversial.

However, the broadest effects are generally achieved by phosphorylation. Indeed, virtually every known second messenger pathway activates at least one protein kinase and several also affect PPs (Tables 2 and 3); the extent of this modification is controlled by a balance between these two enzyme groups. Phosphorylation is a major regulatory mechanism in metabolism; glycogen metabolism is one of the best-known examples. Hormones that stimulate glycogen breakdown activate PKA, which initiates a protein kinase cascade leading to the phosphorylation and stimulation of glycogen phosphorylase. In addition, PKA and other kinases modify and inhibit glycogen synthase; that is, glycogen breakdown is activated, while its synthesis is blocked. On the other hand, insulin favors glycogen synthesis; it does so by activating the phosphatases that reverse these phosphorylations. Many other metabolic cycles are also regulated by this modification.

In addition, phosphorylation can affect other cellular processes: it can alter the function of various channels and transporters and trigger the breakdown of the cytoskeleton.

5.2 Genomic

Hormones and their mediators can also affect gene expression by the same mechanisms described in the previous section (Table 4). For example, nuclear

Tab. 3 The hormone regulation of several protein phosphatases.

Protein phosphatase (PP)	*Regulation*
Serine–threonine phosphatases	
PP1	Subunit composition affects localization
	Phosphorylation, direct or on inhibitory proteins (± depending upon the kinase)
PP2A	Polyamines, ceramide, phosphorylation, and carboxymethylation (+)
	ATP and several oncogene products can shift PP2A from a serine–threonine to a tyrosine phosphatase
PP2B (calcineurin)	Calcium–calmodulin (+)
	Phosphorylation and several immunosuppressants (−)
PP2C	Unknown

SHP	Allosteric activation when its SH2 domain binds a phosphotyrosine
PTP-1B	Direct phosphorylation by RTKs (+)
PEST-PTP	PKA and PKC phosphorylation (−)

Tab. 4 Some transcription factors mediating hormone action.

Transcription factor	*Abbreviation*	*Primary activator(s)*
cAMP response element binding protein	CREB	PKA phosphorylation
Jun-Fos	AP-1	PKC phosphorylation (indirect)
Myc-Max		CK2 and MAPK phosphorylation
Myocyte enhancer factor 2	MEF2	CaM displaces inhibitor
Nuclear factor of activated T-lymphocytes	NFAT	Dephosphorylation by PP2B, a CaM-regulated phosphatase
Nuclear factor for κ genes of B-lymphocytes	NF-κB	PKC phosphorylation of inhibitor protein (indirect)
Nuclear receptors	GR, ER, TR, etc.	Ligand binding by steroids, retinoids, thyroid hormones, etc.
Serum response factor	SRF	CK2 and MAPK phosphorylation
Signal transducers and activators of transcription	Stat	Direct phosphorylation by receptor or soluble tyrosine kinases
Tubby		Sequestered by polyphosphoinositides at plasma membrane until PLC hydrolysis

receptors are actually transcription factors that are allosterically regulated by their ligands, usually hormones but also second messengers like arachidonic acid. Many other transcription factors are controlled by phosphorylation. The simplest mechanism would be for an RTK or a cytokine receptor with associated soluble tyrosine kinase to phosphorylate directly a transcription factor that would then migrate to the nucleus and activate gene expression. The Stat family is activated by such a mechanism (Fig. 6a).

However, most transcription factors are phosphorylated via second messenger pathways. For example, hormones whose activities are mediated by cAMP first activate G_s; the α subunit then stimulates adenylate cyclase, and the resulting accumulation of cAMP activates PKA. Finally, PKA modifies a cAMP response element binding protein (CREB); in particular, the phosphorylation occurs in a TAD that can then recruit a critical transcription coactivator (Fig. 6b).

Phosphorylation can also occur on accessory proteins: NF-κB is a transcription factor frequently associated with defense genes. It is held in the cytoplasm by an inhibitory subunit, IκB. After being modified by PKC-activated kinase, IκB dissociates, allowing NF-κB to translocate to the nucleus, bind its HRE, and activate transcription (Fig. 6c, right). Phosphorylation is not always stimulatory: NFAT, another transcription factor associated with defense genes, is tonically inhibited by phosphorylation. Activation occurs when hormones elevate calcium concentrations that stimulate PP2B (Table 3), leading to the dephosphorylation of NFAT (Fig. 6c, left).

Many second messengers can directly bind transcription factors (Fig. 6c, left). Calcium binds and inhibits a repressor known as *downstream regulator element antagonist modulator* (*DREAM*). CaM displaces Cain, an inhibitor, from the myocyte enhancer factor 2 (MEF2). Tubby is sequestered at the plasma

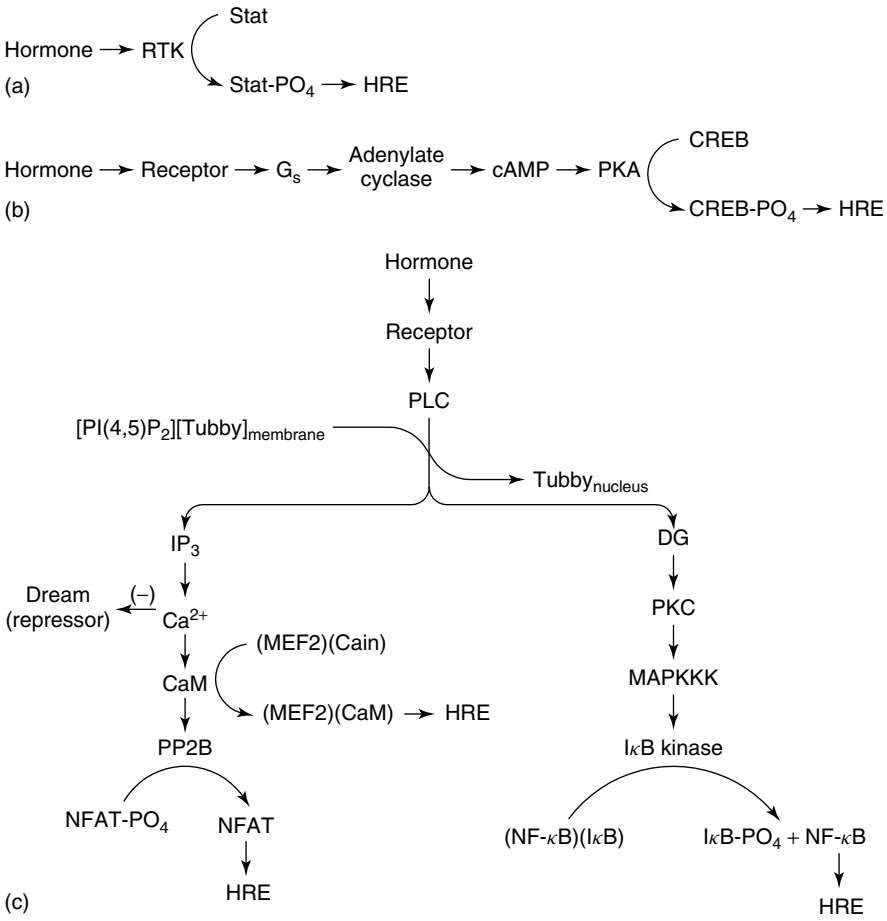

Fig. 6 Activation of several transcription factors by various second messenger pathways: CaM, calmodulin; DG, diacylglycerol; DREAM, downstream regulator element antagonist modulator; HRE, hormone response element; MEF2, myocyte enhancer factor 2; PLC, phospholipase C; RTK, receptor tyrosine kinase. See Tables 2 and 4 for other abbreviations.

membrane by binding to polyphosphoinositide. Hormonal stimulation of PLC hydrolyzes the phospholipid and releases Tubby to migrate to the nucleus and activate transcription.

The reader should be warned that the above discussion is an oversimplification. In fact, many transcription factors may be modified by several different kinases. This cross talk allows for the integration of multiple signals, although it may at times appear confusing. Therefore, this general overview has concentrated only on the dominant regulators of several major pathways.

Finally, hormones can also affect gene expression at posttranscriptional sites. They can induce enzymes that process RNA, binding proteins that stabilize or destabilize mRNA, and activate kinases that can phosphorylate components of the translational machinery.

6
Clinical Applications

Nowhere have the benefits of molecular biology been more obvious than in the diagnosis and management of endocrine diseases. Hormones are so active that their serum concentrations are in the nanomolar range or less, and their receptors rarely exceed more than a few thousand per cell. With such small numbers, conventional protein purification and characterization techniques are inadequate. Most defects in hormones, receptors, and transducers are identified by nucleotide sequencing after amplification by the polymerase chain reaction. Such techniques have been so successful that a review of this size cannot begin to cover all the endocrinopathies whose molecular bases have been determined; however, mention will be made of all the general categories, and a single example of each will be given.

6.1
Endocrine Deficiencies

6.1.1 Hormones

A peptide hormone deficiency can most simply arise from a deletion or mutation in the gene for that hormone. The former occurs with the growth hormone (GH) gene in *isolated GH deficiency, type IA*, and the latter has been reported in the insulin gene in some forms of *diabetes mellitus*. Other mutations may affect the processing of hormones. For example, mutations in the cleavage sites for the signal sequence of parathormone (PTH) or between the different chains of insulin are responsible for *familial isolated hypoparathyroidism* and *hyperproinsulinemia* respectively. Antidiuretic hormone (ADH) concentrates the urine and is synthesized as a polyprotein: the amino terminus forms this hormone, while the carboxy terminus is a transport protein for ADH. Mutations in the transport protein region impair ADH packaging and transport, leading to ADH deficiency (called *familial neurohypophyseal diabetes insipidus*) even though ADH itself is normal. A final processing defect is represented by mutations in the protease responsible for cleaving polyproteins. Adrenocorticotropic hormone (ACTH) is a pituitary hormone that stimulates the adrenal glands to produce steroids; it is synthesized as a polyprotein containing ACTH and several other hormones. The enzyme that cuts out these hormones is defective in *isolated congenital ACTH deficiency*.

Steroids are not coded for by genes; they are synthesized by enzymes. Therefore, steroid deficiencies are actually deficiencies in steroid synthetic enzymes. Defects in virtually every enzyme have been reported and are grouped under the umbrella of *congenital adrenal hyperplasia*. A similar situation exists for the thyroid hormones; defects have been noted both in thyroid peroxidase and its substrate, thyroglobulin, in several forms of *goiter*.

Finally hormones may be deficient because of regulatory defects. Pit-1 is a transcription factor found exclusively in the anterior pituitary gland, and it stimulates transcription of the *GH* gene; mutations in Pit-1 lead to *familial human dwarfism*. Glucokinase represents another regulatory site; this metabolic enzyme phosphorylates glucose as soon as it is transported into the cell. In the insulin-secreting β-cells of the pancreas, it doubles as a glucose sensor; elevated glucose levels stimulate the secretion of insulin, which then activates metabolic pathways that store the glucose. Mutations in glucokinase prevent the β-cell from detecting glucose, and insulin fails to be secreted; this form of

diabetes is called *maturity onset diabetes of the young*.

6.1.2 Receptors

In many endocrinopathies, the hormone is normal in structure and concentration, but the target tissue is unresponsive. The first cellular component that the hormone encounters is its receptor, and many defects in this element have been reported. Mutations for almost every nuclear receptor have been described, but those for the androgen receptor are the most numerous, probably because androgen function is not essential for survival. The default body plan for mammals is female; males are created when the testes produce androgens that masculinize the embryo. Partially active androgen receptors leave this process incomplete, producing a *male pseudohermaphrodite*. Totally inactive mutants result in a phenotypic female; this condition is called *testicular feminization*.

Membrane receptors can also be defective. Mutations in the insulin receptor, an RTK, lead to severe forms of diabetes mellitus; those in the GH receptor, a cytokine receptor, result in *Laron dwarfism*; and defects in the ADH receptor, a GPCR, produce *hereditary nephrogenic diabetes insipidus*. Even mutations in ligand-gated ion channels have been identified: the glycine receptor is a chloride channel whose activation hyperpolarizes, and therefore inhibits, neurons. Defects in this receptor leave stimulatory signals unchecked and are responsible for *hereditary hyperekplexia*, a disease characterized by overstimulation of the muscles and an exaggerated startle response.

6.1.3 Transduction

Examples of defective transduction pathways are much rarer. Many different hormones activate the same mediators; therefore, mutations in these second messenger pathways would have much greater effects than the absence of a single hormone or its receptor. Most reported defects have been in special isoforms restricted to certain tissues or organs so that their effects would be limited. For example, the eye possesses several unique isoenzymes of the phosphoinositide pathway; mutations in any of these components would only result in blindness. Another example is found in the kidneys where ADH stimulates the translocation of a water channel, aquaporin-2, from the cellular interior to the plasmalemma. This allows the kidney tubule to resorb water and concentrate urine. In one form of *nephrogenic diabetes insipidus*, this water channel is mutationally inactivated. ADH and its receptor are normal, but the kidney cannot respond to ADH because the water channel is no longer operational.

One of the few examples of a generalized defect is *pseudohypoparathyroidism, type IA*, where G_s is inactive or absent. Although this defect would affect any hormone utilizing cAMP as a second messenger, the actions of PTH appear to be most severely impacted. PTH maintains serum calcium levels by resorbing this mineral from bone and recovering it from urine. The loss of responsiveness to PTH leads to skeletal abnormalities.

6.2 Endocrine Excesses

Perhaps, more fascinating than loss-of-function mutations are those that actually lead to overactivity. No mutations that increase the intrinsic activity of a hormone have been reported, but mutations affecting hormone processing are known. A mutant preproneuropeptide Y

exhibits enhanced cleavage from its precursor, resulting in higher levels, endothelial proliferation, and an increased risk of atherosclerosis. A mutant fibroblast growth factor 23 is resistant to proteolysis, and its accumulation leads *to autosomal dominant hypophosphatemic rickets*. Altered catabolism also forms the basis for one form of *hyperaldosteronism*. Aldosterone is a steroid that regulates sodium metabolism; excess aldosterone activity causes sodium to be retained and blood pressure to rise. The aldosterone receptor cannot distinguish between aldosterone and cortisol; since cortisol is present in serum at concentrations much higher than aldosterone, cortisol should flood the aldosterone receptor and keep it continuously stimulated. This does not happen because in target tissues, 11β-hydroxysteroid dehydrogenase rapidly metabolizes cortisol before it can reach the receptor. However, a deficiency of this enzyme leads to the overstimulation of the aldosterone receptor by cortisol.

Another form of hyperaldosteronism is caused by a regulatory mutation. The enzymes that synthesize cortisol and aldosterone are very homologous and their genes are contiguous on the chromosome; ACTH stimulates the former via elements in the 5′ end of the gene. Because of the similarity between the genes, they can accidentally pair up during meiosis, resulting in a nonreciprocal crossing-over. In this way, the gene for aldosterone synthase acquires the regulatory region from the other gene and the latter is lost. Because there is no cortisol, ACTH is elevated; but instead of stimulating cortisol synthesis, it stimulates aldosterone synthase. The patient is treated with cortisol, which feeds back to inhibit ACTH secretion; the aldosterone synthase gene, in turn, is shut off. For this reason, the disease is called *glucocorticoid remediable aldosteronism*.

Finally, hormone secretion can be elevated by faulty negative feedback. As noted above, PTH restores serum calcium concentrations by resorbing it from bones and recovering it from urine. As calcium levels rise, PTH secretion shuts off. A mutant calcium sensor blocks this negative feedback and results in the persistent secretion of PTH, which in turn elevates calcium. The heterozygous state, called *familial hypocalciuric hypercalcemia*, manifests only mild symptoms, but the homozygous condition, called *neonatal severe hyperparathyroidism*, produces a more grave disease.

Mutations can also render receptors constitutively active in the absence of their natural ligand. Those in RTKs often produce tumors, since these receptors usually serve growth factors; they are discussed in this context in Section 6.3. An activating mutation in the erythropoietin receptor eliminates the binding site for the phosphatase that normally deactivates it. The hyperactive receptor overstimulates red blood cell production and elevates the hematocrit; this disease is called *primary familial polycythemia*. Several activating mutations have also been reported in GPCRs; they usually occur in either the transmembrane helices or the cytosolic loops. The former are thought to mimic the ligand-occupied state, while the latter improve coupling to G-proteins. Luteinizing hormone (LH) is a pituitary hormone that stimulates the gonads to produce sex steroids. Activating mutations in its receptor can stimulate steroidogenesis prematurely, giving rise to *familial male precocious puberty*. Because women require a second hormone for estrogen production, mutations in the LH receptor alone do not lead to any symptoms.

Finally, activating mutations have been identified in a transducer. G_s inactivates itself when it hydrolyzes GTP to GDP (see Section 4.1); mutations that adversely affect its GTPase activity without altering its ability to interact with its effectors would result in the constitutive activation of G_s. Because G_s is integral to so many pathways, this type of mutation would be lethal if it were genomic; however, somatic mutations would produce a genetic mosaic in which only some cells would possess the defective gene. Individuals with this type of G_s mosaicism have *McCune–Albright syndrome* and have symptoms reflective of overstimulation of all the hormones that utilize cAMP as a second messenger. These hormones include those that stimulate pigment cells (café au lait spots), the gonads (precocious puberty), the thyroid gland (hyperthyroidism), the adrenal glands (adrenal hyperplasia), and bone (dysplasias).

6.3 Oncogenesis

Cancer diagnosis and treatment is another area where molecular endocrinology has made substantial contributions.

6.3.1 Oncogenes

Before defining an oncogene, it would be advantageous to define a protooncogene. A protooncogene is a normal cellular gene that is usually involved in cell growth. If this gene is mutated so that its product is constitutively active, then cell growth may proceed unchecked and tumor formation may occur. Such a modified gene is now called an *oncogene*. Oncogenes may arise spontaneously within the organism's genome or they may be introduced by oncogenic viruses. In the latter case, it is believed that these viruses originally acquired protooncogenes from their hosts and later converted them to oncogenes because they conferred some reproductive advantage on the virus. For example, a rapidly dividing cell may have an abundance of replicative machinery that the virus can then commandeer for itself.

Since most viruses have small genomes, it would be more efficient for the virus to plug into a preexisting proliferative pathway than to control all the processes of cell division itself. As such, most oncogenes are components of the growth factor pathway. Some are GHs, like the platelet-derived growth factor and the fibroblast growth factor. Others are receptors for growth factors; the most abundant groups are the RTKs and the cytokine receptors with their associated tyrosine kinases. Many mutations involve deletions of the extracellular domain and other changes that favor aggregation. Remember, the only function of the ligand in these receptors is to induce oligomerization, which then activates the intrinsic or associated tyrosine kinases. Other mutations may incapacitate autoinhibitory sites within the kinases.

Second messengers are also well represented, especially the small G-proteins such as Ras and various adaptors. In the case of G-proteins, mutations often occur in the GAP binding region; without the ability to interact with GAP, GTP cannot be hydrolyzed and the G-proteins remain permanently active. Finally, several oncogenes are transcription factors. Although most of these factors are constitutively active like the receptors and G-proteins, a few are dominant inhibitors. The active factors are involved with cell proliferation, while the inhibitory ones are involved with either differentiation or defense responses. Because a cell has limited

resources, growth and differentiation often compete with each other; therefore, tumor formation requires both the induction of cell proliferation and the inhibition of differentiation. Examples of factors in the latter group include a mutated thyroid hormone receptor and a mosaic retinoic acid receptor.

6.3.2 Tumor Resistance to Therapy

When hormone target tissues become malignant, they often retain their endocrine sensitivity. Such tumors can be initially treated by hormone therapy: breast cancer may respond to antiestrogens; prostate cancer, to antiandrogens; and leukemias and lymphomas, to glucocorticoids. Hormone therapy is not only effective but also among the most easily tolerated treatments, because of its relative lack of undesirable side effects. Unfortunately, the effectiveness of this therapy is too often short lived as the tumor eventually develops resistance. Quantitative and structural studies of nuclear receptors can help determine which of these tumors will initially respond to hormone therapy and can also explain why many of them later become resistant.

Many resistant tumors have been found to have inactive receptors. The simplest case is seen in leukemias and lymphomas, which undergo apoptosis in response to glucocorticoids. Resistant tumors either lack glucocorticoid receptors or possess defective receptors and, therefore, can no longer respond to these steroids. It is felt that these deletions and mutations arise spontaneously; those that inactivate the receptor offer a selective advantage by allowing the cells that have them to evade the cytotoxic effects of glucocorticoids. Such cells survive and reproduce to create a cancer resistant to these steroids.

On the other hand, breast and prostate cancers are dependent upon sex steroids for survival; as such, they are treated by hormone ablation or antagonists. Therefore, simple deletion or inactivation of the receptor would prove detrimental to the survival of the cancer. Two types of mutations are observed in these cases. First, some mutations render the receptor constitutively active regardless of the presence or absence of hormone agonists or antagonists. Second, mutations in the ligand-binding domain may reduce the binding specificity of the receptor so as to allow other steroids, or even steroid antagonists, to activate the receptor. In either instance, the tumors have either reduced or eliminated hormone dependence.

7 Perspectives

Single cells require careful regulation of metabolism, growth, and reproduction in order to survive in a competitive and dangerous environment. The development of multicellularity introduced the additional problem of intercellular communications to coordinate these processes. Nature's frugal solution was to simply couple external chemical signals to these preexisting intracellular regulators, which then became second messengers. As such, knowledge about molecular endocrinology is knowledge about the very essence of how cells control all their internal functions. In addition, this information provides valuable insights into ourselves via the various disease states that can now be explained by molecular biology. Therefore, molecular endocrinology affords a critical understanding of many basic physiological processes of life.

Keywords

Endocytosis
The process by which cells move extracellular molecules and portions of their own plasma membrane into the cell interior (cytosol). This occurs through formation of a small invagination of the plasma membrane into a bud, which ultimately separates to form an endocytic vesicle in the cytoplasm.

Clathrin
A large protein complex composed of three heavy and three light chains; it provides a coat for a class of endocytic vesicles.

Caveolae
Small flask-shaped invaginations on the plasma membrane that are rich in cholesterol, sphingolipids, and the protein caveolin. These structures are presumed to be relatively static and comprise a major clathrin-independent endocytic pathway.

Adaptor Protein
A class of protein that plays a critical role in connecting the plasma membrane and specific membrane proteins with components of the endocytic machinery and clathrin to ensure efficient endocytosis of particular molecules.

Endosome
An intermediate compartment of the endocytic pathway that is the destination of endocytic vesicles. Sorting events occur at endosomes that dictate the next destination of each protein or molecule that has been internalized.

Multivesicular Body
A late endosome in which sorting events have occurred, which result in the formation of small vesicles within the endosome; these vesicles generally contain membrane proteins that will be degraded upon delivery to the lumen of the lysosome.

Lysosome
An organelle highly enriched in hydrolases that degrade lipids, proteins, carbohydrates, and nucleic acids into their monomer components for reuse in the cell. Lysosomes are frequently the final destination of endocytosed material.

Interaction with the environment is crucial for the survival of cells, through communication with one another via signaling molecules (e.g. hormones) and nutrient acquisition. One major problem a cell must overcome is how to *selectively* carry out exchanges with the external environment and still maintain an internal composition that is chemically distinct. The plasma membrane (PM) makes this selectivity possible. While water and small molecules can cross the lipid bilayer by diffusion or transport through the lipid bilayer, larger macromolecules enter a cell by a different mechanism. Endocytosis is the process by which cells internalize extracellular material by forming intracellular membrane-bound vesicles originating from the PM, and subsequently sort the vesicle contents to the appropriate destination. Internalized material includes membrane proteins, PM lipids, and extracellular fluid, and may also include other cells or apoptotic cell fragments,

parasites, viruses, nutrients, or activated PM signaling complexes. The critical importance of endocytosis to such a wide variety of physiological processes has made it a focus of intensive investigation by scientists with diverse backgrounds and interests. Indeed, studies of the endocytic pathway are among the most highly interdisciplinary and methodologically innovative in all of modern biology, and the field is currently in a state of exciting and rapid advance. In this chapter, we attempt to summarize our current understanding of the endocytic pathway, focusing on recent progress in elucidating fundamental mechanisms of endocytic membrane trafficking and highlighting selected examples of their diverse physiological functions.

1 Overview of Endocytosis: Common Themes

A generic overview of the endocytic pathway is depicted in Fig. 1. Endocytosis begins at the cell surface with the deformation and vesiculation of a region of the PM into which various membrane constituents (cargo) are sequestered.

The newly formed vesicle is then transported to and fuses with a network of organelles called *early endosomes* (EE), where cargo destined for degradation is sorted out from material to be recycled. Recycling of material to the PM can occur from either the sorting endosome or the recycling endosome. Cargo destined for degradation is delivered to late endosomes (LE) (which intersect with the biosynthetic pathway) and then to lysosomes where they are degraded.

The endocytic pathway comprises a complex network of membrane trafficking events consisting of repeated cycles of membrane deformation, coat assembly and disassembly, vesicular transport, and membrane fusion (Fig. 2). Each of these events requires a tightly regulated interplay among numerous protein components. From the recent structural and functional characterization of various proteins involved in endocytosis have emerged several common themes in endocytic trafficking.

One major theme is that many endocytic proteins are *multimodular*; that is, they contain multiple binding sites – many of which are of low affinity – for other proteins or lipids, thus coordinating complex cross-linking events that stabilize a network or web of protein interactions. Among the many binding domains identified, lipid binding modules have received a great deal of recent attention, especially those that bind phosphoinositides localized at the PM, endosomes, lysosome, and Golgi. These proteins include both lipid modifying enzymes and proteins that serve as linkers between membranes and coat constituents.

A second theme in endocytosis is the compartmentalization of endocytic organelles into specific, biochemically distinct domains that underlie the selective sorting of proteins and lipids. Compartmentalization is provided by differential lipid sorting into tubules and large or small vesicles, and by specific localization of members of a group of regulatory molecules known as Rab GTPases, which temporally and spatially coordinate vesicular transport and docking/fusion events throughout the secretory and endocytic pathways. To date, 12 Rab proteins have

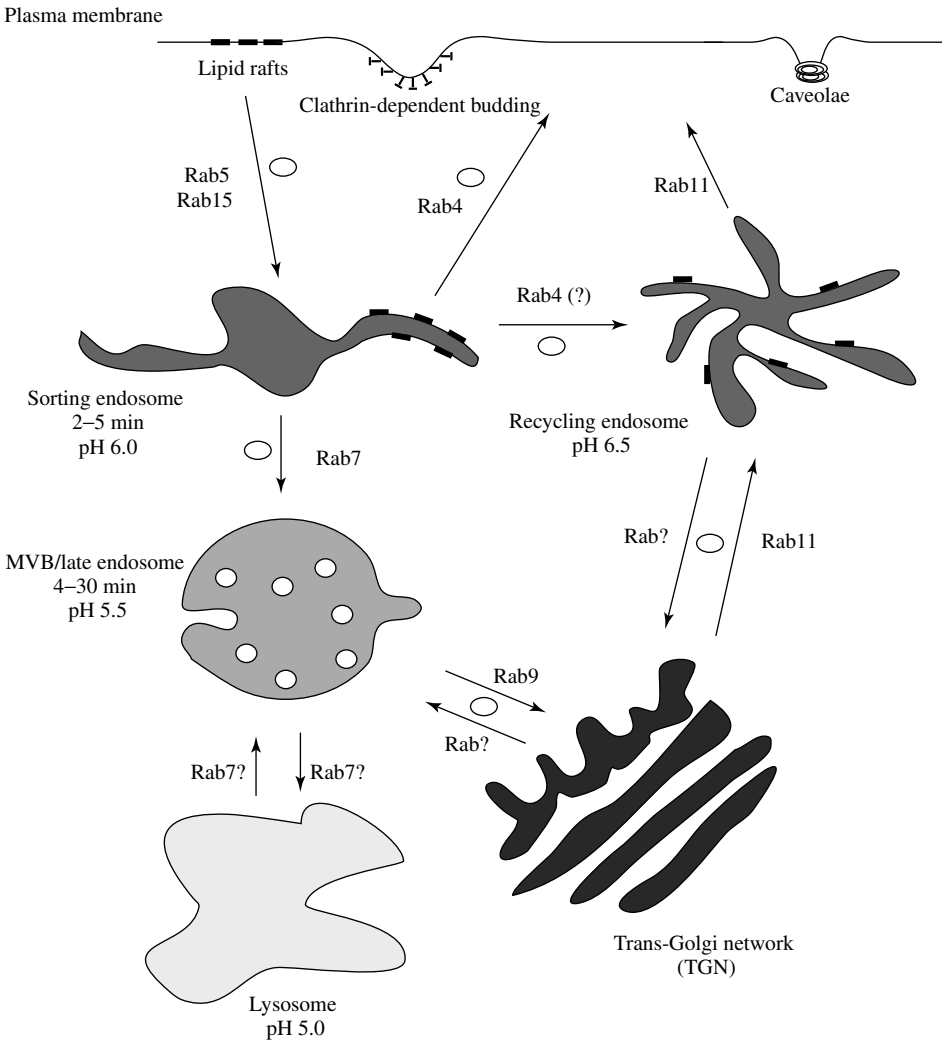

Fig. 1 The endocytic pathway. Endocytosis begins at the PM where membrane invaginations containing cargo give rise to vesicles, which fuse with a network of organelles called *early endosomes*. Here, cargo destined for degradation is sorted out from material to be recycled. Recycling of material to the PM can occur from either the *sorting endosome* or the *recycling endosome*. Cargo destined for degradation is delivered to *late endosomes* (which intersect with the biosynthetic pathway) and then to *lysosomes* where they are degraded.

been localized to the endocytic pathway; some of these are depicted in Fig. 1 (see also Table 1). Rab GTPase activity and membrane localization are tightly regulated by various accessory proteins.

Ubiquitylation modifications have recently been implicated in facilitating various events in the endocytic pathway and thus represent a third theme. At the early steps of endocytosis, monoubiquitylation

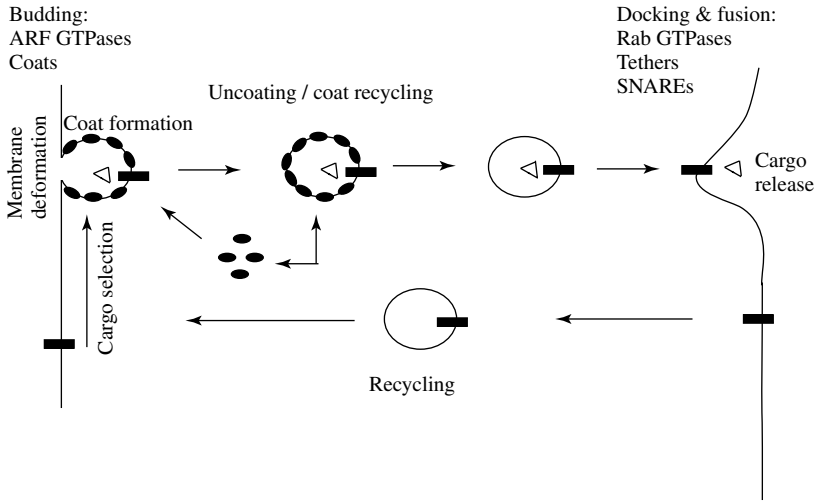

Fig. 2 Membrane trafficking themes in endocytosis. The endocytic pathway comprises a complex network of membrane trafficking events consisting of repeated cycles of cargo selection/membrane deformation, coat assembly and disassembly, vesicular transport, and membrane fusion (based on a figure from Mellman, I., Warren, G. (2000). The road taken: past and future foundations of membrane traffic, *Cell*. **100**, 99–112).

of the cytosolic tail of certain membrane receptors allows them to be recognized by and bind endocytic machinery components. Later in the pathway, ubiquitylation targets certain membrane proteins to the luminal vesicles of LEs. Recent studies have shown that some endocytic machinery components themselves receive covalent ubiquitin modifications, though the function of this remains to be elucidated.

A fourth and final common theme in endocytosis is its relationship to the cytoskeleton. The actin cytoskeleton plays a fundamental role in coordinating the internalization step of endocytosis, as well as in vesicular transport from the PM to EE. The precise role(s) for actin in these events remains to be determined; however, it is clear that a dynamic cycle of polymerization/depolymerization of actin filaments is essential. Microtubules also play important roles, especially at later stages of the endocytic pathway and in polarized epithelial cells, although the microtubule-based motor proteins involved in many of these pathways are not yet known.

This chapter will summarize our current understanding of the cellular and molecular mechanisms of endocytosis, with primary focus on mammalian and yeast systems, and will highlight selected examples illustrating the diverse physiological functions of endocytosis.

2 Internalization

2.1 Clathrin-mediated Endocytosis

The best characterized mechanism of endocytosis is mediated by clathrin-coated pits and vesicles. These structures were first identified by their characteristic

Tab. 1 Proteins involved in endocytosis.

Protein	***Binding properties/function***
I. Cargo recruitment/coat assembly	
Clathrin	Coat protein; driving force for vesicle formation
AP-2	Binds lipids, clathrin, cytosolic tails of certain receptors, accessory factors (e.g. epsin, Eps15); an adaptor protein
Epsin	Binds lipids, clathrin, AP-2, ubiquitin, and Eps15; an accessory protein
Eps15	Binds Epsin, AP-2, ubiquitin, SH3-domain proteins; an accessory protein
AP180/CALM	Binds lipids, clathrin; promotes assembly of clathrin cages
Synaptotagmin	Membrane protein, interacts with SNARE machinery; may serve as ''docking site'' for clathrin-coat formation
II. Membrane curvature and fission	
Amphiphysin	Binds lipids, clathrin, AP-2, endophilin, dynamin, and synaptojanin; recruits and coassembles with dynamin at bud neck
Endophilin	Binds lipids, synaptojanin, and dynamin; a lysophosphatidic acid acyl transferase that induces membrane curvature
Dynamin	Binds lipids, endophilin, amphiphysin; GTPase that mediates fission of vesicles from the PM
III. Coat disassembly and vesicular transport	
Hsc70	Molecular chaperone; disrupts clathrin–clathrin interactions, disassembles triskelia
Auxilin	DnaJ domain family member; binds clathrin and AP-2; recruits and stimulates Hsc70
Synaptojanin	Binds lipids, amphiphysin, Eps15, and endophilin; a phosphoinositide-5 phosphatase
Dynamin	Interacts with actin cytoskeleton components to mediate vesicular propulsion from the PM
Arp2/3	Stimulates actin nucleation; involved in vesicular movement
IV. Rabs in endosomal sorting	

Protein	***Organelle***	***Function***
Rab4	EE and RE	Recycling from EE and RE
Rab5	PM, vesicles, EE,	PM to EE
Rab7	LE/lysosomes	LE to lysosome (?)
Rab9	LE	LE to TGN
Rab11	RE	RE to PM
Rab15	EE and RE	EE to lysosome; RE to PM
Rab17	ARE	Apical recycling in epithelial cells
Rab25	ARE	Apical recycling in epithelial cells

Note: PM: plasma membrane; EE: early endosome; RE: recycling endosome; LE: late endosome; TGN: trans-Golgi network; ARE: apical recycling endosome.

appearance, observed in transmission electron micrographs of osmium-stained tissue sections, and were subsequently isolated from tissue homogenates using subcellular fractionation techniques. The identification of clathrin heavy chain as the major protein component of the dense membrane coat associated with these endocytic vesicles laid the groundwork for increasingly sophisticated biochemical and structural studies, which continue to this day.

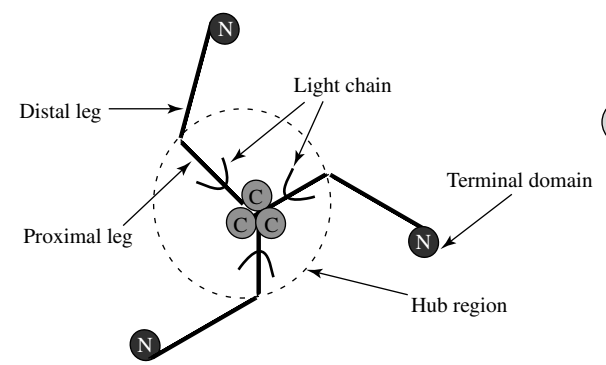
Clathrin-coated vesicles (CCVs) are short-lived intermediates ($t_{1/2} < 2$ min) that are produced in a complex process involving the formation of clathrin-coated invaginations (or coated pits) in the PM, scission of these invaginations from the PM to form endocytic vesicles, and subsequent dissociation of the clathrin-containing coat structure. The ''primary'' endocytic vesicles thus formed fuse rapidly with other uncoated endocytic vesicles and with the limiting membrane of a heterogeneous population of larger membrane structures, called *early endosomes*, which are located in the peripheral cytoplasm. The coat components liberated into the cytoplasm during the uncoating process are thought to recycle to the PM, where they can participate in subsequent rounds of endocytosis (see Fig. 2).

2.2 Structure of the Clathrin Coat

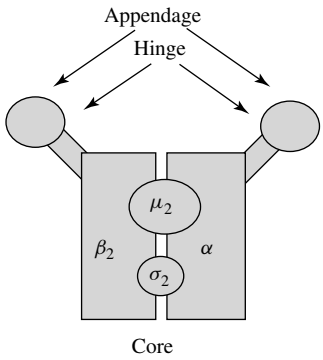
The structural backbone of the clathrin coat is a ''triskelion'' composed of three radially arranged spokes composed of clathrin heavy chains (~190 kDa) and three associated light chains (20–25 kDa) (Fig. 3). The aminoterminal domain of clathrin heavy chain forms a globular region at the periphery of each spoke. The carboxyterminal region of each clathrin heavy chain self-assembles to form the central hub of the triskelion structure. One light chain polypeptide binds to the middle portion of each heavy chain. The heavy chains contribute to the major structural integrity of the triskelion. The light chains are thought to serve primarily a regulatory function in the process of clathrin assembly and disassembly. The characteristic hexagonal and pentagonal lattice structure of the clathrin coat, which is elegantly revealed by rapid freeze-etch electron microscopy, is composed of assemblies of interlocking triskelia. Under certain conditions, purified clathrin can form similar latticelike structures spontaneously *in vitro*, suggesting that the clathrin assembly might contribute to the energetics of endocytosis and that the clathrin assembly process must be highly regulated *in vivo*.

2.3 Other Protein Components of the Clathrin Coat

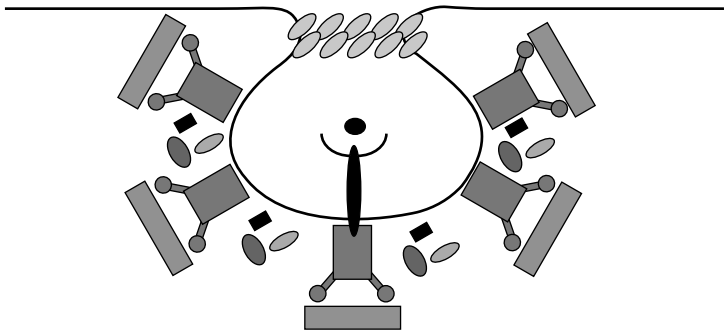
There is a long and growing list of proteins known to associate with the clathrin-coat structure (Table 1). The first such proteins to be identified were the assembly proteins, so-named for their ability to promote the assembly of purified clathrin into lattices *in vitro*, suggesting that they regulate coat formation *in vivo*. Assembly protein complexes termed AP-1 and AP-2 are present in stoichiometric amounts relative to clathrin in purified coated vesicles, but these proteins are segregated in functionally distinct subsets of coated vesicles. AP-2 is associated with endocytic coated vesicles formed at the PM. In contrast, AP-1 is associated with coated vesicles formed at the Golgi apparatus, which mediate transport to the endolysosomal system. AP-1 and AP-2

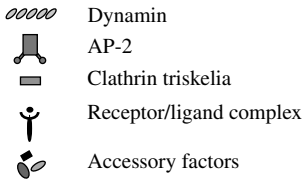


(a) Clathrin triskelion



(b) Adaptor complex (AP-2)





(c) Clathrin-coated pit

Fig. 3 Clathrin-coat components. (a) Structure of a clathrin triskelion. The clathrin triskelion is composed of three radially arranged spokes composed of clathrin heavy chains (~190 kDa) and three associated light chains (20–25 kDa). The aminoterminal domain of clathrin heavy chain forms a globular region at the periphery of each spoke. The carboxyterminal region of each clathrin heavy chain self-assembles to form the central "hub" of the triskelion structure. One light chain polypeptide binds to a central portion of each heavy chain. (b) Structure of AP-2. AP-2 is a heterotetrameric complex consisting of two large subunits (α and β_2; ~100 kDa), one medium subunit (μ_2; ~50 kDa) and one small subunit (σ_2; ~25 kDa). The N-termini of the α and β_2 subunits fold into a compact core structure, and the C-termini form an exposed appendage (or "ear") domain, separated from the core by a flexible hinge region. (c) Simplified diagram of a clathrin-coated pit. Studies indicate that AP-2 is located in a layer between the coated vesicle membrane and the surrounding lattice of assembled clathrin triskelia, suggesting that AP-2 physically links the clathrin lattice to the endocytic membrane. Dynamin localizes to the bud neck to promote fission. Various other accessory factors are depicted.

share a similar heterotetrameric structure, with two large subunits (~100 kDa), one medium subunit (~50 kDa), and one small subunit (~25 kDa).

The subunits of AP-2 are termed α and β_2 (large), μ_2 (medium), and σ_2 (small). Structural and biochemical studies indicate that the aminoterminal portions of the α, β_2, and μ_2 subunits and all of the σ_2 subunits are folded into a compact core (or "brick") structure; the carboxyerminal portion of the α- and β_2-subunits forms an exposed appendage (or ear domain) separated from the core by a flexible hinge region, while the carboxyerminal portion of the μ_2 subunit presents a cargo-binding interface (Fig. 3). The hinge region of the β_2-subunit interacts with clathrin. The core regions are thought to interact with proteins that control the subcellular localization (i.e. PM or Golgi) of APs, and the appendage regions are thought to interact with a number of other proteins that regulate coat formation or function (see Sect. 2.4). Structural studies indicate that AP-2 is located between the coated vesicle membrane and the surrounding lattice of assembled clathrin triskelia, suggesting that AP-2 physically links the clathrin lattice to the endocytic membrane. The AP-2 α-subunit is thought to bind phosphoinositides in the lipid bilayer involved in controlling the dynamics of coated pit assembly at specific sites on the plasma membrane. Recent structural studies suggest that assembled AP-2 contains two phosphoinositide binding sites.

Two other protein complexes, termed AP-3 and AP-4, share sequence homology and a similar heterotetrameric organization with AP-1 and AP-2. However, AP-3 and AP-4 promote clathrin lattice formation weakly or not at all *in vitro*, and whether or not they interact with clathrin coats *in vivo* is controversial. A group of proteins called GGAs (Golgi localized, γ-ear-containing Arf-binding proteins) have sequence homology to classical APs, but exist as monomers and associate with CCVs much less stably than AP-1 or AP-2. A variety of additional proteins associated with varying affinities to clathrin-coated membranes, including dynamin, amphiphysin, synaptojanin, endophilin, intersectin, Eps15, epsin, AP180/CALM, and nonvisual (β-) arrestins. These proteins are proposed to serving a variety of regulatory functions in endocytic coat assembly, membrane dynamics, and cargo selection. In many cases, these proteins associate with several other protein components of the clathrin coat via multiple, low-affinity interactions. A number of coat-associated proteins, in addition to AP-2, also bind to phosphoinositides. The complexity of protein–protein and protein–lipid interactions makes it challenging to define the precise role played by any particular protein interaction and suggests that certain coat-associated proteins may serve multiple functions, and some functions may be performed by multiple proteins. *In vitro* reconstitution experiments and studies in genetically tractable systems like yeast, *Drosophila*, and *Caenorhabitis elegans* will be needed to dissect the physiological role for many of these factors.

2.4 Mechanism of Endocytic Cargo Selection

Clathrin-coated pits exhibit considerable selectivity in their endocytosis of specific membrane cargo. Early insight into the biochemical basis of endocytic cargo selection came from studies of patients suffering from familial hypercholesterolemia (discussed in Sect. 12.1). A severe form

of this disease was associated with a mutation of a tyrosine-containing sequence present in the cytoplasmic tail of the low-density lipoprotein (LDL) particle receptor. Mutation of this tyrosine residue both impaired LDL uptake and changed the distribution of the LDL receptors (LDLRs) from coated pit localization to a uniform distribution in the PM. Similar tyrosine-containing endocytic signals have been identified in a number of other rapidly endocytosing membrane proteins. Additional endocytic signals, such as the dileucine motif, are biochemically distinct from tyrosine-containing sorting signals but also promote the concentration of specific proteins in clathrin-coated membranes. Many endocytic signals, including tyrosine and dileucine-containing sequences, function by binding to the AP-2 assembly protein. Analogous sequences bind to AP-1, and thereby promote packaging of specific membrane cargo into Golgi-derived coated vesicles. For this reason AP-1 and AP-2, named initially for their ability to promote clathrin assembly, are also commonly called *adaptor* proteins, because they link specific cargo to the forming clathrin coat. Phosphorylation of the μ_2-subunit of AP-2 by the adaptor-associated kinase AAK1, enhances binding of tyrosine-based endocytosis signals, indicating that the interaction of adaptor proteins with specific membrane cargo can be regulated.

A number of other clathrin-associated proteins, in addition to AP-2, can serve as endocytic adaptors for recruiting specific membrane cargo into CCVs. For example, nonvisual (β-) arrestins, which bind to G-protein-coupled signaling receptors after ligand-induced activation and phosphorylation, promote endocytosis of receptors via clathrin-coated pits by also binding to clathrin or AP-2 as well as to phosphoinositides. Another clathrin-binding protein, epsin, contains ubiquitin-interacting motifs (UIMs), which may recognize ubiquitylated cargo, as well as Asn-Pro-Pre (NPF) containing sequences that bind to Eps15 homology (EH) domains present in various coat-associated proteins such as Eps15. The currently favored models suggest that epsins function as endocytic adaptors for certain membrane cargo.

2.5 Mechanism of Endocytic Coat Formation

The ability of purified clathrin and AP-2 to self-assemble into extended lattices *in vitro* suggested that clathrin-coat formation *in vivo* is driven by polymerization. However, the initiation of clathrin-coat assembly appears to be highly regulated *in vivo*, as a large fraction of clathrin exists at steady state as ''free'' triskelions in the cytoplasm, while clathrin coats transiently form and dissociate in specific regions of the PM. The factors controlling the temporal and spatial specificity of clathrin-coat formation are not well understood but are generally believed to involve the initiation of clathrin polymerization at defined ''docking sites'' in the PM. Synaptotagmin I/II are integral membrane synaptic vesicle proteins that bind to AP-2 via a lipid and Ca^{2+}-binding C2b domain, and are proposed to function as docking sites for clathrin/AP-2 coat formation in neurons to facilitate synaptic vesicle membrane recycling. However, synaptotagmin I/II expression is restricted to neural cell types, and it is not known if a ubiquitously expressed synaptotagmin (many candidates exist) provides an analogous docking site for clathrin-coat initiation in nonneural cells. Another possible type of docking site may involve membrane lipids

such as PtdIns(4,5)P_2, which may be generated in restricted regions of the PM; this phosphoinositide binds a number of coat-associated proteins, including AP-2, dynamin, and epsin.

Although they bind to AP-2, classical endocytic signals present in cargo proteins are not likely to act as docking sites as a primary mechanism for localizing clathrin-coat formation. Overexpressing cargo proteins typically does not affect the density of clathrin-coated pits in the PM; the localization of these integral membrane proteins appears to be determined by the localization of clathrin-coat formation and not vice versa. Nevertheless, membrane cargo that presents tyrosine-containing endocytic signals can promote the association of synaptotagmin with AP-2, suggesting that cargo proteins may contribute to a more complex mechanism regulating coat formation involving multiple protein interactions.

Arf-family GTPases regulate the formation of Golgi-derived (clathrin/AP-1-associated) coated vesicles by a mechanism that may involve Arf-dependent activation of phospholipase D and/or recruitment of GGA proteins, which have been proposed as functioning both in coat formation as well as in cargo recruitment at the Golgi. An analogous GTPase regulating endocytic clathrin/AP-2 coat formation *in vivo* has not been identified, although recent data suggest that Arf6 stimulates the PtdIns(4,5)P2-synthesizing PI5-kinase enzyme that in turn leads to recruitment of AP-2. Endocytic coat formation also appears to be regulated by the phosphorylation state of AP-2. Unassembled AP-2 in the cytosol is phosphorylated on the β_2-subunit. Dephosphorylation of this subunit is thought to occur specifically at the PM and promotes AP-2 assembly with clathrin.

2.6 Mechanism of Membrane Curvature and Fission

Endocytosis via clathrin-coated pits involves the formation of deep membrane invaginations followed by scission of the bilayer to form the nascent clathrin-coated vesicle. These processes of membrane invagination and scission represent distinct steps in a multistep endocytic mechanism. Positive curvature (bulging inward toward the cytoplasm) of invaginated membranes is generally thought to be promoted by self-assembly of the clathrin lattice itself.

A mechanism for generating endocytic membrane curvature was proposed recently on the basis of structural studies of the clathrin coat-associated protein epsin. An aminoterminal portion of epsin was observed to fold into an amphipathic alpha-helix specifically when bound by phosphoinositide. This helical structure inserts into the lipid bilayer and can mediate membrane tubulation *in vitro*. In this case, however, epsin has been suggested to play a role in inducing phosphoinositide-regulated positive curvature to initiate formation of coated pits.

A number of models have been proposed for the mechanism mediating the negative membrane curvature present at the edges of invaginated coated pits, where dynamin, amphiphysin, and endophilin are concentrated. It is suggested that these proteins induce negative curvature by mechanically constricting the membrane in this region. This hypothesis is supported by the ability of these proteins to self-assemble and cause tubulation of liposome membranes *in vitro* and the requirement of endophilin for endocytic membrane invagination *in vivo*. Additionally, purified endophilin possesses

lysophosphatidic acid acyl transferase activity, suggesting that endophilin induces membrane curvature by modifying phospholipids at the site of neck constriction. The extent to which the bilayer-deforming properties of endophilin depend on this enzymatic activity has been debated.

Studies of *shibire* mutant *Drosophila* revealed that they had a mutation in the large GTPase dynamin, which is required for the reuptake of PM from the nerve terminal. Subsequent studies established an essential role of dynamin in endocytic membrane scission in various mammalian cell types. Dynamin self-assembles into rings around the neck of a clathrin-coated pit, suggesting that dynamin may function as a GTP-regulated force-generator to mechanically constrict and perhaps shear the invaginated, coated pit from the PM. Whether dynamin functions as a direct force-generator or instead functions to regulate a distinct mechanochemical effector remains unresolved. It is also not known if a dynamin-related GTPase is involved in endocytosis in yeast, although actin is essential for fission of endocytic membranes in yeast. Various roles have been proposed for actin in clathrin-mediated endocytosis occurring in mammalian cells, but whether or not actin is essential for endocytosis in mammals has remained controversial. A recent study using evanescent field microscopy to image coated pit formation in living mammalian fibroblasts revealed a transient accumulation of polymerized actin around the coated pit just after dynamin recruitment and just prior to vesicle excision from the PM. These data suggest that dynamin coordinates local actin polymerization to provide the mechanical force necessary to propel nascent coated vesicles away from the PM into the cytoplasm.

3 Clathrin-independent Endocytosis

The existence of clathrin-independent endocytic processes was first indicated by morphological observations of endocytic structures not associated with a characteristic electron-dense membrane coat, and has been confirmed using a variety of manipulations that differentially inhibit clathrin-dependent and -independent endocytic mechanisms with varying degrees of specificity. Interestingly, there appears to be regulatory communication between distinct pathways that allow adaptation and upregulation of one pathway when the other is blocked. To further complicate matters, there is evidence of the existence of multiple clathrin-independent endocytic pathways. While none of these mechanisms is understood as well as clathrin-mediated endocytosis, macropinocytosis and endocytosis of caveolae have been characterized in some detail.

3.1 Macropinocytosis

Macropinocytosis is a prominent endocytic pathway in macrophages and can also be induced by growth factors or infectious agents in other cell types. Macropinocytosis is so-named because it is characterized by the uptake of endocytosed cargo in vesicular structures that are typically much larger (up to 5 μm in diameter) than CCVs (<100 nm). Macropinosomes generally form from actin-rich ruffled regions of the PM and, like phagocytosis, macropinocytosis is strongly inhibited by agents such as cytochalasin that disrupt actin polymerization. This is in contrast to the limited or variable effects of such agents on endocytosis involving clathrin-coated pits or caveolae. Macropinocytosis is not inhibited

by overexpression of dominant-negative mutant versions of proteins (dynamin, clathrin, and Eps15) involved in clathrin-mediated endocytosis. The small GTPase Arf6, which modulates actin dynamics at the cell cortex, also appears to regulate the formation of macropinosomes. This activity of Arf6 appears to further distinguish the mechanism of macropinocytosis from clathrin-mediated endocytosis, although Arf6 can also modulate clathrin-mediated endocytosis in some cases.

3.2 Caveolae

Caveolae is a term used to describe small (50–80-nm diameter) invaginations of the PM that were observed initially in electron microscopic studies of endothelial cells and have since been recognized in several other cell types. These structures are enriched in glycosphingolipids and cholesterol and possess a proteinaceous membrane coat that is composed primarily of the cholesterol-binding protein caveolin. Caveolin is an integral membrane protein, unlike clathrin-coat components, which are peripherally associated with the membrane, and is required for the formation and structural integrity of caveolae. While caveolae were initially proposed not to undergo classical endocytosis, but rather to serve as a conduit across closely opposed endothelial membranes, there is increasing evidence that caveolae can indeed undergo dynamin-dependent fission from the PM. However, recent Fluorescence Recovery After Photobleaching (FRAP) analysis using GFP-tagged caveolin indicates that caveolae are highly immobile structures and are thus not likely to play a significant role in constitutive endocytosis. Endocytosis via caveolae appears to be primarily ligand/signal-induced and is a major internalization pathway for certain toxins and viruses. Interestingly, during internalization of the SV40 virus, caveolae may mediate an alternative endocytic pathway leading directly to the ER (endoplasmic reticulum) and bypassing conventional endosomes.

4 Vesicular Trafficking

4.1 Uncoating of CCVs

The events occurring after the initial internalization step have been characterized most thoroughly for endocytosis mediated by CCVs. CCVs must be uncoated to expose proteins important for fusion with EEs, and to allow for recycling of coat components for further rounds of internalization (Fig. 2). Extensive *in vitro* studies have demonstrated that uncoating of CCVs is mediated primarily by two proteins: the molecular chaperone, ATPase Hsc70, and auxilin, a clathrin-binding protein belonging to the Dna J family. Auxilin 1 is neuron specific, while auxilin 2 (aka GAK, or Cyclin G-associated Kinase), a ubiquitously expressed isoform discovered later, contains an AAK1-related protein kinase domain of unknown function. Yeast and *C. elegans* homologs of auxilin have also been identified. In the general mechanism for Hsc70/Auxilin-mediated CCV uncoating, auxilin binds assembled clathrin (and AP-2 in some cases), recruits Hsc70 via its J domain, then stimulates Hsc70's ATPase activity. Hsc70 disrupts clathrin–clathrin interactions to uncoat CCVs, and remains bound to disassembled clathrin, possibly to initiate reassembly, while auxilin is released and recycled. *In vitro* studies

using dominant-negative forms of Hsc70 suggest that it assists in other clathrin-dependent functions including endosomal trafficking. The phosphoinositide-5 phosphatase, synaptojanin 1, also plays a role in CCV uncoating; its enzymatic activity (degrading PtdIns(4,5)P_2 to PtdIns4P) helps disrupt membrane-clathrin coat interactions.

4.2 PM to Cytosol

Clathrin-coated vesicles, after undergoing rapid, chaperone-dependent uncoating in the peripheral cytoplasm, become highly fusogenic. These ''nascent'' endocytic vesicles fuse rapidly with a pleiomorphic set of endomembranes called *early endosomes* (EEs). EEs are highly dynamic structures in which continuous membrane fusion and fission events can be observed using live-cell microscopy. A large volume of membrane traffic passes through EEs, and cargo molecules are efficiently sorted between divergent membrane pathways after entry into the EEs. Thus, it is believed that the membrane dynamics that occur in the early endocytic pathway are highly specific and regulated.

Shortly after a nascent endocytic vesicle is formed, it moves from the PM to the EEs through a thin region of peripheral cytoplasm that contains a dense network of actin, which may contribute to endocytic vesicle motility in the cortical cytoplasm via actin-based motors, such as myosin I and other myosins, as well as motility driven directly by asymmetric actin polymerization on the endosome membrane. Dynamin may also provide a link between scission of nascent vesicles and the asymmetric stimulation of Arp2/3-dependent actin polymerization for vesicle propulsion. Recent evidence also suggests roles for unconventional myosin VI in endocytosis.

4.3 Cytosol to Early Endosome

Once a nascent endocytic vesicle is in close physical proximity to the EE membrane, a number of mechanisms controlling the specificity and efficiency of the membrane fusion follow. Purified early endocytic membranes fuse efficiently with EEs *in vitro* (''homotypic'' fusion), but fusion with later endocytic structures occurs with much lower efficiency (''heterotypic'' fusion). A variety of experimental approaches, notably genetic studies of membrane trafficking in yeast and *in vitro* reconstitution of endocytic fusion in extracts prepared from mammalian cells and yeast, have revealed important roles in EE fusion played by tethers, Rab-family GTPases, SNAREs, and phosphoinositides.

N-ethylmaleimide sensitive factor (NSF) (Sec18p), the AAA-family ATPase-mediating disassembly of SNARE complexes is required for membrane transport from early to late endosomes. A number of SNARE proteins are localized selectively to specific populations of endosome membranes, suggesting an important role for SNAREs in controlling the specificity of endocytic membrane fusion. However, to date, the degree to which specific SNARE complex formation determines the selectivity of endocytic membrane fusion *in vivo* has not been determined. Moreover, there is considerable evidence that additional factors contribute to the specificity of endocytic membrane fusion, particularly the Rab family of small GTPases and their associated proteins.

The Rab5 GTPase is selectively localized to EEs and is thought to control the recruitment of a number of other important proteins to the endosome membrane. Mutations that impair GTP hydrolysis on Rab5 (and thus render the protein constitutively active) enhance endocytosis and produce enlarged endosomes. Inactive Rab5 inhibits homotypic fusion of EEs, whereas activated Rab5 promotes this process. Interaction cloning and affinity chromatography methods have identified multiple putative Rab5 effectors. Intriguingly, roles have also been observed for a complex of Rab5-GDI (guanine-nucleotide dissociation inhibitor) in the initial formation of CCVs *in vivo*.

The Rab5 effector, Rabaptin-5, binds to Rab5-GTP in solution and binds to endosomes in a Rab5- and GTP-dependent manner. Rabaptin-5 also binds to the Rab5 GEF Rabex-5, suggesting a synergistic mechanism by which Rab5 activation may be amplified on the endosome membrane. The Rabaptin/Rabex complex can also interact with GGA proteins in a bipartite manner that occludes GGA interaction with clathrin, suggesting that GGAs provide a link between cargo selection in Golgi-derived CCVs and tethering/fusion with endosomes after uncoating. Rabaptin-5 also binds to Rab4, a homologous GTPase that modulates recycling of membrane cargo from EEs to the PM (see Sect. 5); thus, Rabaptin-5 may define functionally distinct endosomal microdomains and coordinate distinct Rab-dependent membrane events involving communication between them. Another cytoplasmic protein that binds preferentially to Rab5-GTP is the early endosome antigen-1 (EEA1), a protein identified as an autoantigen in lupus patients and later shown to regulate endosomal traffic. EEA1 is recruited to the endosome membrane by Rab5-GTP, is essential for efficient fusion of EEs *in vitro* and can promote endosome fusion even in the absence of Rab5 or other cytoplasmic proteins when added to endosomes in high concentration. EEA1 is not detectably associated with nascent endocytic vesicles, yet it is required for efficient fusion of these vesicles with EEs *in vitro*, suggesting a role for EEA1 in determining the directionality of endocytic membrane transport.

Genetic studies of Vps34p in yeast identified a critical role for phosphoinositide 3-kinase in membrane trafficking to the vacuole. Pharmacological inhibitors of type I PI3K activity have profound effects on endocytic trafficking in mammalian cells. EEA1 contains an "FYVE"-type zinc-finger domain (named for homology to Fab1, YOTB, Vac1, and EEA1) that binds with high affinity to 3-phosphoinositides that are enriched in the EE membrane. Efficient recruitment of EEA1 to EEs *in vivo* requires both FYVE domain-mediated binding 3-phosphoinositides and binding of Rab5-GTP via a distinct pair of protein binding domains, leading to synergistic regulation of endosome fusion.

Another binding partner of EEA1 is the endosome-enriched t-SNARE (or Q-SNARE) syntaxin-13. EEA1 can be detected together with syntaxin-13 in a large complex that also contains Rab5 (and several other Rab5-binding proteins). Interestingly, a synthetic peptide that interferes with EEA1/syntaxin-13 binding inhibits EE fusion *in vitro*. These observations suggest that EEA1 may mediate Rab5 and phosphoinositide-dependent membrane fusion by influencing SNARE complex formation on the endosome membrane.

5
The Early Endosomal System

The endosomal system consists of membrane-bound compartments that receive, sort, and release cargo-containing vesicles throughout the endocytic pathway. Early endosomes are the single entry point and first sorting station in the endocytic pathway, and cargo reaches them within 2 to 5 min following internalization. These endosomes are so far known to comprise two subcompartments: sorting endosomes and recycling endosomes.

5.1
Sorting Endosomes

Internalized material is first delivered to the sorting endosome, also referred to as the *tubulovesicular endosome* or the *compartment of uncoupling receptor from ligand* (CURL). This compartment exhibits a high degree of homotypic fusion capacity and is tubulovesicular in morphology, consisting of thin tubules (50–60-nm diameter) that emanate from large vesicles (200–400-nm diameter). The mildly acidic lumen (pH 6.0) of the sorting endosomes promotes the dissociation of many ligands from their recycling receptors. Immediately following dissociation, recycling receptors are sorted away ($t_{1/2} = 2.5$ min) from their ligands and transported through the recycling pathway, while ligands and downregulated receptors are transported through the degradation pathway.

The membranes of sorting endosomes are organized into morphologically and biochemically distinct compartments that are believed to be essential for their sorting functions. For example, recycling receptors are often segregated into tubular regions, while their soluble ligands remain in the lumen of globular/vesicular regions. Regulation of this compartmentalization is thought to depend on the localization of specific molecular machinery. As described above, the Rab family of GTPases comprises a group of regulatory molecules that differentially localize to distinct subdomains of the organelles within the endocytic and exocytic pathways, recruiting specific effector molecules to each membrane domain they inhabit.

Sorting endosomes contain two other Rab GTPases: Rab15 and Rab4. Elferink and colleagues revealed a role for Rab15 in EE function. This GTPase colocalizes with Rab5 on sorting endosomes, and also localizes to recycling endosomes (see Sect. 5.2). Interestingly, the effects on endocytosis caused by overexpression of wild type and mutant forms of Rab15 are in direct contrast to those caused by Rab5 overexpression. Overexpression of constitutively active Rab15 (GTP bound) inhibits internalization of fluid phase marker, while overexpression of constitutively inactive Rab15 mutants (N12I, T22N) increases rates of both internalization and recycling pathways. At sorting endosomes, Rab15 may be an inhibitory GTPase, possibly by negatively regulating Rab5 function. How this regulation occurs has yet to be determined, since interactions between Rab15 and known Rab5 effectors have not yet been identified. Rab4 localizes to the tubular regions of sorting endosomes, which receive cargo within 5 min of internalization. Rab4 mediates ''rapid'' or direct recycling from the sorting endosome to the PM, which is distinct from the ''slower'' recycling route taken through the recycling endosomes. Since Rabaptin5 binds both Rab5 and Rab4, it has been suggested as coordinating the directing of cargo between the distinct sorting domains of the sorting endosome.

Differential sorting of lipids between EE subcompartments can occur independently of Rab GTPases. Elegant studies by Maxfield and colleagues showed that different lipid analogs, varying solely in the length and/or saturation of their hydrophobic tails, sorted to distinct endosomal compartments. Specifically, lipid analogs with longer (16-carbon) saturated tails were delivered to LEs, while those with shorter (12-carbon) saturated tails were mainly found in recycling compartments. This type of sorting would provide an energetically economical mechanism for sorting of certain types of molecules; however, as mentioned, protein–protein/protein–lipid interactions most likely provide additional modulation of these events.

5.2 Recycling Endosomes

In addition to membrane lipids, certain membrane receptors are also recycled, which allows for their reuse in further cycles of ligand binding and endocytosis. In fact, while the lysosomal targeting pathway is better characterized, more than 90% of endocytosed material is recycled to the PM. A classic example of a recycling membrane protein is the transferrin receptor (TfR). This receptor binds iron-bound transferrin at the cell surface, and following the release of iron in the mildly acidic sorting endosome, the iron-free TfR-transferrin complex is transported back to the PM. Owing to clustering in clathrin-coated pits, approximately 50% of TfR molecules on the cell surface can be internalized in less than 5 min, after which TfR is recycled.

Two recycling pathways have been identified: one in which the majority of endocytosed transferrin is returned to the PM directly from the sorting endosome through a ''rapid'' recycling pathway, and another in which the remaining transferrin accumulates in tubulovesicular structures located near the microtubule organizing center, prior to its return to the surface. These pericentriolar structures receive cargo within 2 to 5 min of internalization. They are labeled only with recycling receptors and not with lysosome-targeted receptors (or fluid phase markers) and are slightly more basic than the sorting endosome (pH 6.4–6.5), and were thus distinguished from the sorting endosome as recycling endosomes – also known as the *endocytic recycling compartment* (ERC).

In contrast to Rab4 (described above), Rab11 plays an important role in the ''slower'' recycling pathway to the PM and colocalizes with Tfn at pericentriolar recycling endosomes. A novel family of Rab11-interacting proteins called *FIPs* was identified recently, which share little homology outside of a conserved Rab11 binding domain, and appear to form mutually exclusive complexes with Rab11 *in vivo*. Unlike typical Rab effector proteins, FIPs do not rely on Rab11 for membrane binding, and it is proposed that these proteins function to recruit Rab11 to specific subdomains of the ERC.

5.2.1 Other Proteins Implicated in Recycling

RME1 A genetic screen in *C. elegans* identified Ce-Rme1 as an EH domain protein required for endocytosis and normal ERC morphology. Chinese hamster ovary (CHO) cells, GFP-tagged Ce-Rme1, and the mouse homolog m-Rme1 (also called *EHD-1*) each localize to the PM and transferrin-positive vesicles, but primarily concentrate at the perinuclear ERC. m-Rme1 with a mutation in the N-terminal nucleotide binding domain (G65R) no

longer localizes to the ERC, and instead is cytoplasmic, whereas a mutation near the EH domain (G429R) not only localizes to, but also alters, the morphology of the ERC. The G429R mutant also retards both transferrin recycling and recycling of the protein TGN38, which travels to the trans-Golgi network (TGN) from the PM through the ERC.

Rcy1 A visual screen of the viable deletion strains of *Saccharomyces cerevisiae* identified the protein Rcy1, which, through a fluorescence assay used to measure real-time recycling in yeast, was demonstrated to be required for recycling of PM lipids and proteins. Interestingly, Rcy1 contains an F-box motif, which is implicated in facilitating an interaction between target proteins and the ubiquitin ligase, SKP1/cullin/F-box (SCF). The precise connection between Rcy1, SCF, and recycling remains to be determined, but it is a compelling prediction given the multiple roles for ubiquitin in regulating endocytosis at many levels.

5.3 Transport from Early Endosomes

Transport of material along the endosomal pathway occurs in two ways. During *vesicular transport*, material is exchanged between relatively stable endosomal organelles in the form of intermediate vesicles. There is evidence to suggest that membrane protein transport from sorting endosomes to recycling endosomes occurs simply by default, following bulk lipid flow. However, numerous studies also provide convincing evidence to support tubulovesicular-mediated transport mechanisms. A recent study identified a sizeable pool of vesicles called *endocytic small vesicles* (ESVs) that derive from the EEs and are involved in recycling. At steady state, these vesicles labeled neither with sorting endosomal markers like Rab5 and EEA1, nor with the recycling endosome marker Rab11, contained Rab4, the v-SNARE cellubrevin, and recycling membrane proteins (e.g. TfR). The presence of Rab4 in ESVs is intriguing, since Sönnichsen et al. found that this GTPase preferentially localizes to tubular regions of the sorting endosome, where recycling material is proposed to segregate. A role for coat proteins in the formation of the ESVs has not been clear, and preliminary data suggested that ESV formation also may not involve Arf GTPase-mediated coat recruitment. ESVs may serve as transport vesicles for recycling material from the sorting endosome to either the recycling endosome or directly to the PM.

In contrast to distinct carriers such as ESVs that traffic from sorting to recycling endosomes, EE to LE traffic occurs via *maturation*, in which lysosomally targeted ligands remain associated with sorting endosomes, which eventually mature into later compartments through acidification and removal of material that is recycled to earlier compartments. *In vitro* studies by Gruenberg and colleagues showed a requirement for the coatomer protein complex (COPI) in the maturation of early to late endosomes via intermediate compartments (or perhaps, distinct transport intermediates) called *endocytic carrier vesicles* (ECVs). COPI, which is recruited by ARF1 GTPase, is better known for its functions in the early secretory pathway. COPI consists of seven proteins (α, β, β', γ, δ, ε, and ζ), and most but not all of these components are required for ECV formation. ECV biogenesis also appears to require endosomal acidification, and COPI/ARF1 association with EEs is pH dependent. Endosomal acidification

is mediated by a vacuolar H^+-ATPase. It is proposed that acidification controls EE functions by stimulating assembly of COPI coats, possibly through a specialized transmembrane pH sensor protein. The physiological consequences of defective endosomal acidification are discussed in Sect 12.

Other studies suggest that EEs may contain two distinct populations of clathrin coats: one involved in budding from tubular structures to form recycling vesicles, and the other, a flat clathrin coat involved in sorting cargo for lysosomal targeting. This finding illustrates the multiple roles a single protein can play in the endocytic pathway and the complexity of cargo sorting and transport mechanisms.

6 Endocytosis in Polarized Epithelial Cells

Polarized epithelial cells have biochemically distinct PM domains at their apical and basolateral surfaces that are separated by tight junctions that form a diffusion barrier between the surfaces. Since approximately 50% of a typical epithelial cell surface is endocytosed per hour, correct polarized sorting in the endocytic pathway is crucial for maintenance of cell polarity. Studies with Madin–Darby canine kidney (MDCK) cells confirmed that epithelial cells are able to internalize material from both apical and basolateral PM domains, which is directed to distinct sets of endosomal organelles. Endosomes found in polarized cells include apical early endosomes (AEE) and basolateral early endosomes (BEE), apical recycling endosomes (ARE), a distinct subapical compartment (SAC) in hepatocytes, and a common endosome (CE).

6.1 Trafficking Pathways

A current model for endocytic trafficking in polarized epithelial cells is depicted in Fig. 4, where specific Rab GTPases known to be associated with each compartment are noted. Basolaterally internalized material, including membrane and fluid, first enters the BEE (pH 5.8). Both recycling (e.g. TfR-Tf) and transcytosing (e.g. pIgR-IgA; see Sect. 6.3) materials are then transported to the CE, while material destined for degradation (e.g. fluid phase markers, LDL, and EGF (epidermal growth factor)) is transported to the LEs. The CE, also known as the *common recycling endosome*, has a tubular morphology and serves as a nexus between apical and basolateral membrane traffic. A role for clathrin and a class of epithelial cell-specific adaptor proteins has been demonstrated for the exit of basolateral recycling material from the CE.

Apically internalized material is first delivered to the AEE. From the AEE, material can travel to the ARE for recycling, to the CE for transcytosis, or to the LE/lysosome for degradation. Rab11 and its effector Rip11 have been implicated in apical recycling. Studies with MDCK cells show that the majority of apically internalized fluid phase markers is either recycled or transcytosed, which may be a reflection of the dependence of apical endocytosis on the GTPase ARF6 and its exchange factor, ARNO (ARF nucleotide binding site opener). In contrast, the majority of basolaterally internalized fluid phase marker accumulates in LEs and lysosomes. These differences in endocytic trafficking pathways among the apical and basolateral surfaces are essential for the maintenance of function and polarity in epithelial cells.

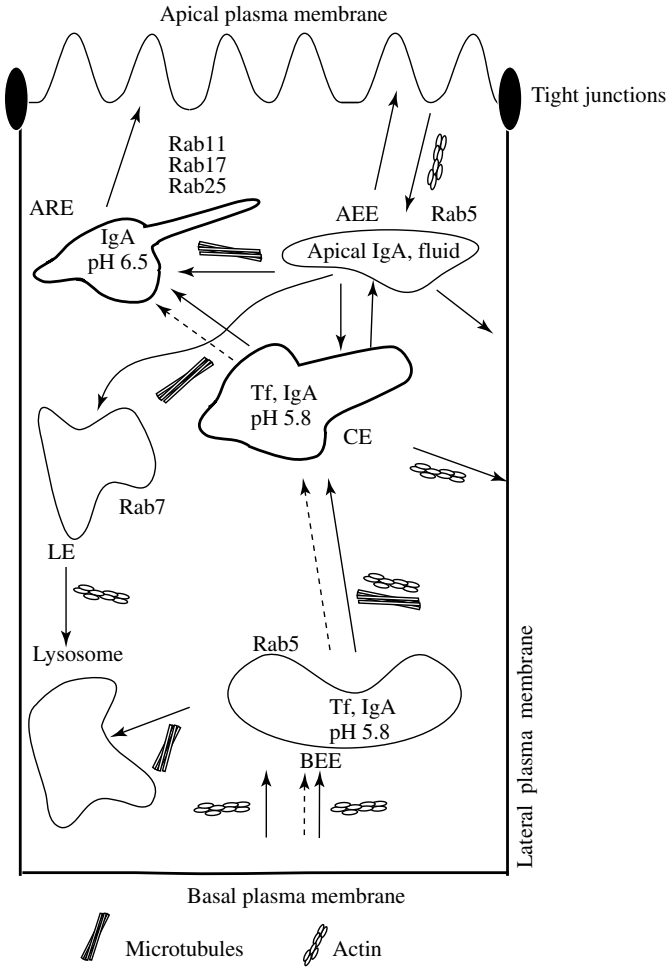


Fig. 4 Endocytic traffic in polarized epithelial cells. Internalization can occur either from the apical or basolateral surface. Internalized material is first delivered to either the AEE or BEE. From the AEE, material can recycle (via the ARE), transcytose (via the CE), or be delivered to the LEs and lysosomes. At the BEE, recycling, transcytosing, and lysosome-directed material are sorted from one another. Recycling from the BEE occurs via the CE. Transcytosing material is delivered from the BEE to the CE, then to the ARE, while lysosome-directed cargo can enter the LE directly from the BEE. Roles for the cytoskeleton (actin or microtubule) are depicted for each step wherever possible, as are resident Rab GTPases.

6.2 Regulation of Endocytosis in Polarized Epithelia

Clathrin-mediated endocytosis (CME) occurs at both apical and basolateral surfaces; however, there are some differences observed between the two subdomains, as already noted above. Studies have also demonstrated differential roles for dynamin in endocytosis at either surface. Two isoforms of dynamin, dyn1 (primarily neuronal) and dyn2 (ubiquitous), differentially localize when expressed in MDCK cells; dyn1 functions at the apical surface, while dyn2 functions at the basolateral surface.

The cytoskeleton plays an important role in endocytic traffic at both membrane domains of polarized epithelial cells. Microtubules, which allow rapid ($\sim$1 μm s^{-1}) movement over long distances, have been implicated in vesicular transport between AEEs and AREs, between AEE/BEEs and LEs, between BEEs and the CE, and during basolateral to apical transcytosis. Actin filaments, which are shorter and support slower movements (0.1 μm s^{-1}), also play an important role in endocytosis. Studies with the actin-perturbing drug cytochalasin D show that apical endocytosis is inhibited, while basolateral endocytosis is unaffected. Interestingly, the actin filament stabilizer, jasplakinolide, stimulated basolateral endocytosis, but did not affect apical endocytosis; this may reflect a difference between the dynamic properties of apical and basolateral actin pools. Differential cytoskeletal dependencies may also underlie differences in internalization rates between the two domains; CME at the apical surface occurs at 20% of the rate (per unit surface area) of that found at the basolateral surface.

6.3 Transcytosis: the IgA Example

The movement of material between the apical and basolateral membrane domains is called *transcytosis*. This process was first shown to transport immunoglobulins (IgG, IgA, and IgM) across epithelial sheets, moving them from the blood into the lumen of the gut to prevent pathogenic invasion of mucosae. Transcytosis is also used to deliver maternal IgG in milk from the gut epithelium to the circulatory system of newborns, and is now known to be a major mechanism by which a variety of macromolecules are delivered to apical surfaces. The transcytotic pathway of the polymeric Ig receptor-dimeric IgA (pIgR-dIgA) complex has been extensively studied and is presented here as an example.

Dimeric IgA (dIgA) is the major immunoglobulin found in mucosal secretions; it is synthesized and secreted by B lymphocytes and then transcytosed across the epithelial cell layer for incorporation into mucus. dIgA first binds the pIgR, located on the basolateral surface (in contact with the blood) of mucosal epithelia. The complex is then endocytosed via clathrin-coated pits, followed by delivery to the BEE. From here, pIgR-dIgA travels to the CE; however, it is presently unclear from this point whether the complex is delivered directly from the CE to the apical surface, or whether it must first enter the ARE. At the apical surface, pIgR is proteolytically cleaved by a thiol-dependent protease, releasing the extracellular portion of the pIgR still bound to dIgA into secretions.

7 MVBs and the Late Endosomal System

For material destined for degradation, processing, or further sorting, the next

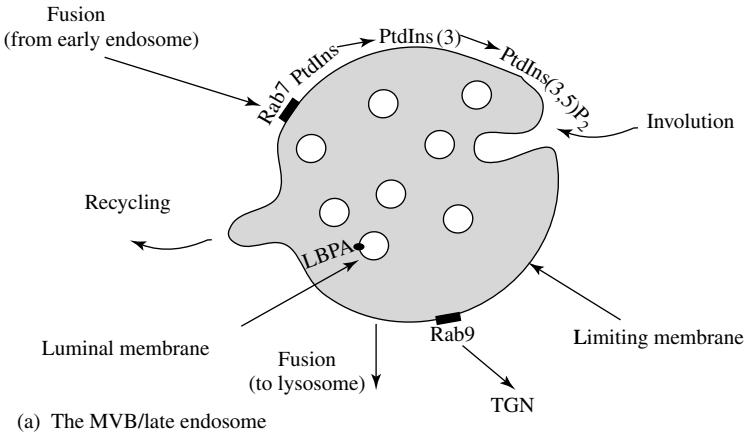
step in the endocytic pathway is the late endosomal system, which comprises juxtanuclear, prelysosomal organelles that typically receive cargo within 5 to 30 min following endocytosis. Late endosomes are the major intersection of the biosynthetic and endocytic pathways. As for EEs, LEs are a network of subcompartments consisting of spherical organelles, 0.4 to 0.7 μm in diameter, often containing small luminal vesicles. Though the majority of degradation occurs in lysosomes, evidence suggests that a significant amount of degradation can occur in LEs. LE organelles are variously referred to as endocytic carrier vesicles, late endosomes, multivesicular endosomes and multivesicular bodies (MVBs), and multilamellar bodies. There is still debate about the temporal relationship and defining characteristics of each of these compartments. General characteristics of MVBs/LE are depicted in Fig. 5(a). Like MVBs, LEs contain luminal vesicles; the limiting membrane is relatively depleted of cholesterol and sphingomyelin, while the internal vesicle membranes are highly enriched in lysobisphosphatidic acid (LBPA). Its hydrophobicity and propensity to bend membranes implicates LBPA in the formation of LEs. PI3P is also found on the inner membranes of LEs, mainly in regions poor in LBPA.

7.1 Late Endosomes

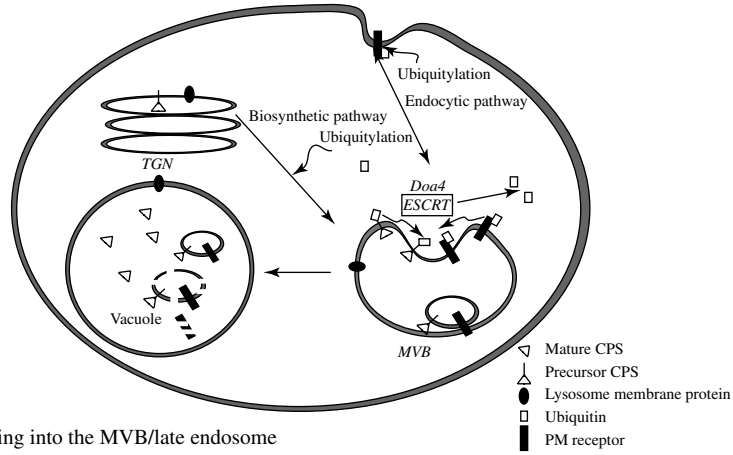
In addition to endocytosed cargo, LEs also receive traffic from the TGN consisting of an assortment of newly synthesized lysosomal acid hydrolases and integral membrane glycoproteins. Mannose-6-phosphate Receptors (MPR) sequester mannose-6-phosphate-tagged, soluble lysosomal hydrolases at the TGN, and mediate their sorting into CCVs. GGAs interact with the cytosolic tails of MPRs to coordinate this sorting. It is likely that these TGN-derived vesicles first travel to EEs before entering LEs. Consistent with this, the GGAs were shown recently to interact with a Rababtin-5/Rabex-5 complex on EEs. Thus, GGAs may not only be important for cargo selection but also for proper targeting. In contrast, newly synthesized lysosomal integral membrane proteins (LAMPs, LIMPs, and Igps) may travel directly to LEs through association with AP-3 complex at the TGN.

7.2 Sorting into MVBs

A defining feature of the MVBs is their luminal vesicles. These vesicles form by selective incorporation of a subset of proteins on the limiting membrane of the MVB into small vesicles that invaginate into the lumen, forming luminal vesicles (see Fig. 5(b)). The MVB pathway is required for delivery of both biosynthetic and endocytic membrane proteins to the yeast vacuole. The sorting of specific membrane proteins into luminal vesicles is an important pathway for proteolytic processing and degradation of membrane proteins, but also delivers certain vacuolar hydrolases that become active only after being sorted and processed by this pathway. Genetic studies in yeast have provided significant insight into the mechanisms underlying MVB formation, through the identification of a subset of vacuolar protein sorting (*vps*) mutants that accumulate an exaggerated LE termed the "*class E compartment.*" Recently, members of the class E *vps* family have been implicated in mediating vesicular sorting into the MVB. Vps23, Vps28, and Vps37 form a 350-kDa complex, termed the *endosomal sorting complex*



(a) The MVB/late endosome



(b) Sorting into the MVB/late endosome

Fig. 5 Structure and sorting of MVB/late endosomes. (a) MVB/late endosomes comprise a network of membrane-bound, spherical structures. These organelles are dynamic and at any point may be involved in fusion with traffic from the early endosome (via Rab7) and the TGN (via Rab9), involution of their limiting membranes to form luminal vesicles, or recycling of limiting membrane components. PI3P localizes to limiting membranes, while LBPA localizes to luminal membranes. (b) Sorting into MVB luminal vesicles is mediated by the ESCRT complexes (I, II, and III). Sorting cargo may include PM receptors or biosynthetic material (e.g. CPS). Ubiquitylation serves as a signal for recognition of cargo by ESCRTs; however, deubiquitylation occurs prior to actual internalization into luminal vesicles.

required for transport (*ESCRT*-I). Vps23 contains a ubiquitin conjugating (UBC)-like domain that is required for its function and is proposed to bind to ubiquitylated proteins. Studies have confirmed that ubiquitylation of cargo is important for its sorting into MVB luminal vesicles in yeast. The mammalian homolog of Vps23 is encoded by the tumor susceptibility gene 101 (*tsg101*), which also contains a UBC-like domain. *tsg101* mutants recycle the epidermal growth factor receptor (EGFR) rather

than targeting it to lysosomes, resulting in excessive growth factor signaling, which may explain why these mutant mice are prone to developing tumors (see Sect. 12.4 below).

Two more yeast ESCRT complexes (ESCRT-II and ESCRT-III) were identified through analysis of physical and genetic interactions among the remaining uncharacterized class E Vps proteins. ESCRT-II is a stable 155-kDa complex formed by Vps22, Vps25, and Vps36, while the ESCRT-III complex forms only upon membrane recruitment and consists of two subcomplexes: Snf7/Vps20 and Vps2/Vps24. In the current model for sorting into and formation of luminal vesicles, Vps27 associates with PI3P and ubiquitylated cargo. This in turn is thought to promote the sequential recruitment and activation of the ESCRT-I and ESCRT-II complexes, which interact with and promote the assembly of a large oligomer of ESCRT-III on the membrane. The activity of the ESCRT complexes together results in concentration of cargo into membrane invaginations on the MVB limiting membrane that buds inwardly to form luminal vesicles. Interestingly, in some cell types, HIV virus recruits ESCRT-I during a late stage in its budding from the cell surface. Consistent with this, each of the Class E *VPS* genes has a homolog in mammalian cells.

A model for sorting biosynthetic and endocytic cargo into the MVB is depicted in Fig. 5(b). Carboxypeptidase S (CPS) is a biosynthetic cargo of the yeast MVB pathway. It is first synthesized as a type II integral membrane protein, termed *precursor CPS* (*pCPS*), and is sorted into MVB luminal vesicles. Following fusion of the limiting membrane of the MVB with the vacuole and delivery of pCPS vesicles into the vacuolar lumen, pCPS is cleaved from its transmembrane anchor to yield a mature, soluble enzyme (mCPS). Ubiquitylation of the cytosolic tail is thought to be the signal responsible for determining that a transmembrane protein will be sorted into an MVB luminal vesicle. As mentioned earlier, ubiquitylation of certain membrane receptors at the cell surface precedes their internalization, and they are believed to remain ubiquitylated until their sorting into MVBs. In yeast, this ubiquitylation is mediated by the ubiquitin ligase, Rsp5 (homolog of mammalian Nedd4). It was recently demonstrated that the ubiquitin ligase, Tul1, ubiquitylates CPS and other biosynthetic cargos for MVB sorting. Interestingly, membrane proteins that contain polar residues in their transmembrane domains are also favored for sorting into MVBs. Prior to their inclusion into MVB luminal vesicles, biosynthetic and endocytic cargo are deubiquitylated by the ubiquitin isopeptidase, Doa4, thereby recycling ubiquitin into the cytoplasm.

8 Last Stop: the Lysosome

Lysosomes – spherical, electron-dense organelles of ~0.5 μm diameter – are the major degradative compartment in the cell, and represent the final destination for endocytosed material. These organelles were discovered about 50 years ago, before the early endosomal compartments of the clathrin-dependent endocytic pathway were recognized. A major distinction that defines the difference between lysosomes and LEs is that lysosomes lack the MPR, which cycles between the TGN and LEs. However, some studies suggest that LEs and lysosomes are in dynamic equilibrium.

8.1 The Lysosome Biogenesis Controversy

The mechanism underlying lysosome formation has been a controversial issue for many cell biologists. Early studies proposed that lysosomes formed from the Golgi; however, it is now believed that these organelles derive from endosomal compartments. The three main hypotheses proposed for lysosome biogenesis are depicted in Fig. 6. The *vesicular transport* model is based on membrane trafficking events used in other steps of the endocytic

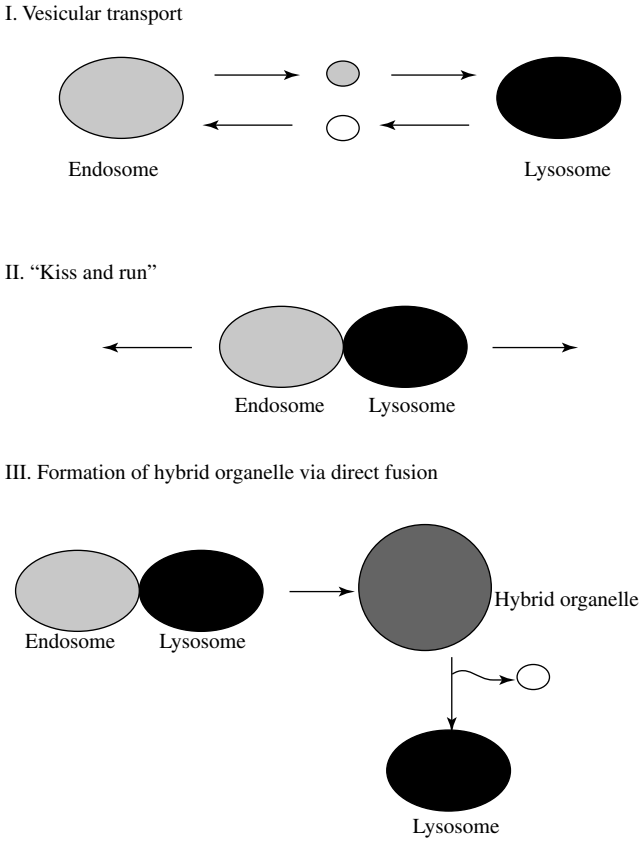


Fig. 6 Models for late endosome–lysosome fusion. Three models exist for late endosome–lysome fusion. (a) Vesicular transport: proposes that late endosomes and lysosomes are stable compartments that receive cargo via fusion with small transport vesicles. There is no experimental evidence to support this model. (b) Kiss and run: transfer of luminal cargo occurs via repeated fusion and fission cycles between LEs and lysosomes. LEs and lysosomes are stable structures, and fusion occurs through transient fusion pores. (c) Direct fusion with formation of a hybrid organelle: fusion between LEs and lysosomes forms a stable hybrid organelle exhibiting intermediate characteristics. There is experimental evidence to support this model.

and secretory pathways and proposes that LEs and lysosomes are stable compartments that receive cargo via fusion with small transport vesicles. While this most likely occurs earlier in the endocytic pathway, there is still no evidence to support this model at later stages.

Another model called *kiss and run* involves repeated fusion and fission cycles between LEs and lysosomes to allow transfer of luminal cargo. This mechanism, proposed by Storrie and Desjardins, was used to explain the differences observed for soluble versus membrane cargo in the rates of delivery between LEs and lysosomes. The third model, *formation of a hybrid organelle via direct fusion*, is best supported by cell-free, *in vitro* fusion assays. When direct fusion was allowed between LEs and lysosomes, a large diameter, membrane-bound organelle was formed with intermediate characteristics between the two compartments and that contained markers for both LE and lysosomes. These studies also provided evidence of LE–lysosome fusion *in vivo* through electron microscopic studies in cultured cells. Also, existence of an LE–lysosome hybrid organelle was observed *in vivo* in normal rat kidney (NRK) cells at steady state, in which approximately 15% of lysosome fusion with LEs formed a hybrid compartment. Thus, LE–lysosome fusion may be the most likely mechanism to occur *in vivo*.

8.2 Rab7 and Endosome–Lysosome Fusion

Work by Bucci and colleagues has demonstrated that the Rab7 GTPase plays a key role in controlling late endocytic traffic. Rab7 localizes to LE–lysosome structures, and overexpression of wild type or GTPase-deficient Rab7 ($Rab7^{Q67L}$) causes aggregation of lysosomes, while expression of dominant-negative $Rab7^{T22N}$ causes their dispersal. A Rab7–GTP binding protein, Rab-interacting lysosomal protein (RILP), which colocalizes with lysosomal markers, was recently identified and is proposed to be an effector protein. Interestingly, in 2001, Jordens et al. showed that RILP expression induces recruitment of dynein–dynactin motor complexes to Rab7-containing LE–lysosome organelles. As other Rab proteins have been shown to interact with motor proteins (e.g. Rab5, Rab6, and Rab27), there may be a general role for Rabs in regulating motor protein recruitment to ensure proper directionality of vesicle transport and fusion.

Formation of LE–lysosome hybrid organelles *in vitro* is ATP, cytosol, and temperature dependent. Cytosol requirements include typical fusion machinery components, including NSF, soluble NSF attachment proteins (SNAP), and a small Rab GTPase. On the basis of EE homotypic fusion studies, a role for SNAREs has also been proposed, though specific SNAREs have yet to be identified. The proteolipid v_0 subunit of the vacuolar H+-ATPase has also been suggested to form a fusion pore necessary for homotypic vacuole fusion. As mentioned earlier, yeast genetics have identifed several proteins involved in vacuolar fusion. Class B and C Vps proteins have been implicated in endosome–vacuole fusion, including t-SNARE machinery (Vam3/Vam7), the Rab GTPase Ypt7, and various Vps proteins that may provide tethering activity.

8.3 Hydrolases, Lamps, and Transporters

There are more than 50 endolysosomal hydrolases including proteases, nucleases, glycosidases, lipases, and phosphatases. Most of these enzymes, like

the yeast vacuolar CPS, are synthesized as precursors that are glycosylated in the ER/Golgi – which may protect them from destruction – followed by removal of a prodomain upon delivery to the lysosome, which generates the mature enzyme. These enzymes are also active only at acidic pHs, and the lysosome lumen is maintained at ~pH 5.0 by vacuolar H^+-ATPase and a redox chain that uses cytoplasmic NADH as an electron donor and oxygen as the final electron acceptor.

LAMPs (lysosomal-associated membrane protein) are the major integral membrane protein constituents of the lysosomal membrane, making up ~50% of the total membrane protein in this organelle. LAMP-1 and LAMP-2 are evolutionarily related type I membrane proteins that have long luminal domains and short cytoplasmic tails which contain lysosome sorting signals. One role of these proteins may be to protect lysosomes from self-hydrolysis and/or prevent escape of hydrolases into the cytoplasm.

Export of proteolysis products, which are recycled for use in anabolic reactions, occurs mainly via transporters. In addition to amino acid transporters, those for carbohydrate monomers, ions, and nucleosides have also been reported. The cysteine transporter is an interesting example. This transporter regulates the flux of cysteine into, rather than out of lysosomes, and its activity may be pH dependent. Cysteine is proposed to serve in regulating the redox potential of lysosomes, as certain enzymes require reducing conditions to be active.

8.4
Secretory Lysosomes

While regulated secretion has long been regarded as unique to specific cell types, the recent finding that conventional lysosomes can fuse with the PM has changed the traditional view of these organelles. Lysosomes that act as Ca^{2+}-dependent secretory granules have been observed in hematopoietic cells such as platelets, neutrophils, macrophages, and cytotoxic T lymphocytes (CTLs). Ca^{2+}-regulated secretion of conventional lysosomes has now been observed in a number of cells, and may serve, in part, to expel undigested lysosomal contents to prevent accumulation of cellular debris.

9
Parasites and the Endocytic Pathway

The endocytic pathway presents several hurdles that parasites must overcome in order to invade and survive successfully in their hosts. First, intracellular parasites must penetrate the PM of the cell, then avoid destruction by the hydrolytic lysosome, and finally, the parasite must employ strategies to evade the immune system. The diversity of intracellular parasites is paralleled by the wide array of solutions to these challenges.

Most commonly, the parasite chooses a professional phagocytic cell as a host, and uses phagocytosis for internalization. For example, the bacterial pathogen *Salmonella* induces robust phagocytosis upon contacting the surface of a macrophage. Other bacteria such as *Listeria* bind to the PM and ''zipper up'' a membrane compartment around themselves as they dive into the cytoplasm. In contrast, much larger protozoan parasites have resorted to strategies that involve the recruitment of intracellular membranes, ranging from granules, ER, recycling endosomes, or lysosomes, each of which can contribute membranes to the forming parasitiphorous vacuole through fusion with the PM at the point of entry.

Exciting recent evidence suggests that the ER plays a more generally utilized role in phagocytosis, and this finding provides satisfactory explanations for many previously puzzling questions. In this new model for the mechanism of pathogen internalization, the ER provides the bulk of the membrane that envelops the pathogen. Under circumstances in which the PM area is insufficient, the ER is an abundant membrane-rich organelle that can supplement the PM for the purpose of covering the pathogen with a lipid bilayer. This also explains how many pathogens can escape degradation by the endolysosomal pathway; the ER is on the biosynthetic pathway and thus the precursor forms of degradative hydrolases are inactive in this compartment. Finally, an ER-dependent component to phagocytosis potentially explains the source of the ER-resident protein calreticulin at the surface of many cells, and also suggests a mechanism for MHC (major histocompatibility complex) Class I presentation of exogenously derived peptides.

In other cell types such as neutrophils, an ER-independent mode of pathogen uptake via phagocytosis predominates. In this case, some pathogens have devised various clever strategies to avoid being destroyed upon delivery to the hydrolytic lysosome. For instance, some pathogens synthesize factors that prevent the maturation of the endosomal compartment they occupy, others convert their compartment to one of a completely novel identity, and still others escape the membranous compartment entirely and spend their lives swimming naked in the cytosol. Access to nutrients is a concern, and some parasites often introduce transporters or pores into the membrane of the parasitiphorous vacuole to allow for diffusion of small molecules such as sugars, nucleotides, and amino acids from the host cytoplasm.

The protozoan parasite, *Trypanosoma cruzi*, has adopted an alternative strategy that allows it to use nearly any cell type as a host, not just professional phagocytes. Upon interaction with the PM of the host cell, *T. cruzi* recruits lysosomes to the cell periphery and induces a Ca^{2+} signal that triggers local fusion of the lysosomes with the PM (see Sect. 8), followed by entry of *T. cruzi* into the cell. This mechanism of internalization explains how *T. cruzi* internalization can occur in cells treated with the actin-disrupting agent, cytochalasin D, which blocks phagocytosis. Once inside the cell, a brief exposure to the acidic pH within the lumen of the lysosome-like compartment induces *T. cruzi* to proceed through its developmental cycle, culminating in its entry into the cytoplasm where it divides and spreads to other cells.

10 Exosomes

Lysosomes are not the only organelles of the later endocytic pathway that can fuse with the PM; MVBs can also undergo exocytosis. When an MVB containing luminal vesicle fuses with the PM, the ''secreted'' luminal vesicles are referred to as *exosomes*. While detailed studies of these small membrane vesicles are still in their infancy, exosomes have generated a great deal of excitement in recent years, primarily due to their potential therapeutic roles in stimulating immune responses. Exosomes were first identified in maturing reticulocytes, which are anucleate and devoid of most intracellular organelles. The release of exosomes provides a mechanism for removing extraneous membrane and transmembrane proteins, such as TfR, to form a mature red blood cell.

It is known that many cell types secrete exosomes, but the physiological role is not yet understood in most cases. In contrast, the role for the exosomes secreted by CTLs is better characterized. It appears that CTLs package perforin and granzymes into exosome membranes for secretion into the immunological synapse formed between the CTL and the target cell it will kill. Many questions persist about exosomes, including their *in vivo* function, and the circumstances under which the MVB-containing exosomes fuse with the PM rather than the lysosome. One recent study suggests that as immature dendritic cells become activated, a pathway is stimulated that delivers MHC II-containing organelles (likely exosomes) to the immune synapses.

The greatest degree of excitement surrounding exosomes is derived from their potential use as an antitumorigenic therapy – exosomes purified from B cells or dendritic cells can stimulate CTLs, and clinical trials suggest that they may be an effective adjuvant for antitumor immunizations. On a different note, exosomes have also been proposed to play important roles in developmental events in *Drosophila*, including establishing morphogen gradients and in proteolytic processing and activation of complicated ligand/receptor partners like Delta/Notch, in which each participant is a transmembrane protein.

11
Endocytosis and Signaling

11.1
Regulated Endocytosis of Signaling Receptors

Many signaling receptors are rapidly endocytosed after ligand-induced activation, such as the EGF receptor tyrosine kinase (EGFR) and the beta-2 adrenergic G-protein-coupled receptor (β2AR), which are endocytosed by clathrin-coated pits. There is also evidence for regulated endocytosis of certain signaling receptors via clathrin and/or dynamin-independent mechanisms. Coated pits and vesicles can contain a mixture of signaling receptors, endocytosed in a ligand-regulated manner, and constitutively endocytosed receptors, such as LDL and the TfRs. This led to the proposal that a major mechanism by which endocytosis of signaling receptors is regulated is by ligand-dependent association with constitutively formed clathrin-coated pits. This hypothesis is consistent with many observations and with the proposed biochemical mechanism of β2AR endocytosis, in which nonvisual (β-) arrestins function as adaptor proteins linking ligand-activated and phosphorylated receptors with the clathrin-coat structure. However, there are some data suggesting that signaling receptors endocytose via a subpopulation of clathrin-coated pits, modify the properties of the coated pits in which they are concentrated, or, in some cases, actually promote the formation of new coated pits *de novo*. Therefore, the degree to which signaling receptors function as ''inert'' endocytic cargo or regulate the endocytic machinery in some way remains a controversial issue.

11.2
Functional Consequences of Signaling Receptor Endocytosis

11.2.1 Receptor Downregulation

One function served by regulated endocytosis of signaling receptors is to rapidly reduce the number of surface receptors accessible to extracellular ligands. In this way, ligand-induced endocytosis is

proposed to serve as a negative feedback mechanism to attenuate (or "downregulate") cellular responsiveness. Downregulation EGFR signaling involves ligand-induced endocytosis of receptors followed by sorting in MVBs and subsequent delivery to lysosomes. Sorting of internalized EGFR in MVBs is mediated by a ubiquitin-dependent mechanism involving mammalian homologs of the yeast class E Vps proteins. Experimental manipulations and naturally occurring mutations that disrupt EGFR sorting by this mechanism result in enhanced growth factor signaling and contribute to tumorigenesis (see Sect. 12.4).

11.2.2 Receptor Resensitization

The functional activity of certain G-protein-coupled receptors, such as the β2AR, can be attenuated rapidly by receptor phosphorylation occurring in the PM, without requiring endocytosis. Ligand-induced endocytosis of the β2AR is proposed to promote the recovery (or "resensitization") of receptor signaling activity, in contrast to the prolonged attenuation of the cell signaling characteristic of downregulation, by delivering phosphorylated receptors to an endosome-associated phosphatase and then to a rapid recycling pathway through which dephosphorylated receptors are returned to the PM in a fully functional state. Nevertheless, ligand-induced endocytosis of many G-protein-coupled receptors (including the β2AR under some conditions) can also lead to receptor trafficking to lysosomes and a more prolonged downregulation of cell signaling. Thus, the degree to which ligand-induced endocytosis via CCVs mediates the functionally opposite processes of resensitization or downregulation depends critically on the sorting of internalized receptors between divergent downstream membrane pathways.

11.2.3 Signaling from Endosomes

In addition to modulating the number or functional activity of signaling receptors in the PM, there is accumulating evidence that certain receptors actually signal from the endosome membrane. Early support for this hypothesis came from biochemical studies suggesting that endocytic vesicles containing internalized receptor tyrosine kinases (such as insulin and EGF receptors) are associated with cytoplasmic proteins that mediate downstream signal transduction from these receptors (such as Grb2 and Src), and more recent studies using fluorescence resonance energy transfer (FRET) imaging indicate that these proteins interact on the endosome membrane. Functional support for this idea comes from studies of neurotrophin signaling via the TrkA receptor tyrosine kinase, which suggest that "signaling endosomes" containing activated receptors and associated signaling molecules carry the receptor-mediated signal for long distances (up to 1 m in certain sensory neurons) from the site of initial receptor activation (in distal axons) to the site of specific effectors (in the cell body) that regulate the expression of genes controlling cell survival.

12 Some Diseases of the Endocytic Pathway

As described earlier, pathogens can exploit the endocytic machinery to gain access into host cells, causing disease. However, a number of genetic diseases result in defects along the endocytic pathway. A few of these diseases are described below.

12.1 Hypercholesterolemia

The majority of the cholesterol required for PM synthesis is acquired through receptor-mediated endocytic uptake. Sixty-five to seventy-five percent of plasma cholesterol is bound to protein in the form of LDL particles for transport through the blood stream, and cells then take up cholesterol via LDLRs. Once in the endosomes, the acidic pH dissociates LDL from its receptor. LDLRs are sorted for recycling, while LDL particles are sorted into the degradation pathway. In lysosomes, cholesteryl esters in the LDL particles are hydrolyzed to free cholesterol, which exits the lysosomes and is available to the cell for new membrane synthesis. Disruption of LDLR-mediated endocytic uptake of cholesterol leads to accumulation of elevated blood cholesterol levels, which can cause formation of atherosclerotic plaques in blood vessels and can lead to strokes and heart attacks. One in 300 to 500 individuals suffers from heterozygous familial hypercholesterolemia (FH), which is associated with mutations in the LDLR gene, as was described earlier. FH patients exhibit abnormally high blood cholesterol levels from birth, throughout adulthood, and often suffer from coronary artery disease and atherosclerosis. A rare autosomal recessive form of hypocholesterolemia (ARH) phenotypically resembles FH, but is not due to mutations in LDLR. Recently, the *ARH* gene was mapped and identified as a putative adaptor protein that contains a phosphotyrosine binding domain (PTB) and interacts directly with the clathrin endocytic machinery. Similar to AP-2, ARH binds to phosphoinositides and clathrin; however, unlike AP-2, ARH can also recognize the LDLR internalization signal, Asn-Pro-X-Tyr (NPXY), through its PTB domain. It is proposed that ARH performs an adaptor function similar to AP-2 for LDLR, and its malfunction disrupts LDL-cholesterol traffic, leading to hypercholesterolemia.

12.2 Defects in Endosomal Acidification and Proximal Tubulopathies

A major function of the proximal tubules of the kidney is filtering hundreds of milligrams of plasma proteins (e.g. albumin and low molecular weight (LMW) proteins), which enter the filtrate via the glomeruli. Since human urine is normally devoid of significant amounts of protein, the reabsorption of proteins by receptor-mediated endocytosis plays an essential role in protein, vitamin, and hormone homeostasis, as well as in the recovery of amino acids. Lignac-de Toni-Debre-Fanconi syndromes (Fanconi syndromes) are disorders that result from the primary dysfunction of the proximal tubule with varying etiologies, but all exhibit defective renal tubular protein reabsorption and tubular proteinuria. These defects are thought to be due primarily to defects in receptor-mediated endocytic pathway in proximal tubules. The apical endocytic apparatus of proximal tubule epithelial cells plays a vital role in the reabsorption and degradation of material from the filtrate. Critical to this endocytic process is endosomal acidification, perturbation of which leads to pathophysiological dysfunction, often resulting in urinary wasting of LMW proteins, electrolytes, and solutes.

The two apical receptors, megalin and cubulin, have been implicated in receptor-mediated endocytosis of ligands such as insulin, HDL, albumin, and vitamin-binding proteins. Indeed, megalin and cubulin knockout mice are defective in tubular

reabsorption, excrete LMW proteins and vitamins in their urine, and are used as animal models for Fanconi syndromes. Proper recycling of megalin and cubulin requires endosomal acidification machinery including the vacuolar H^+-ATPase and CLC-5 chloride ion channels, since dissociation of receptor from ligand in endosomes occurs at low pHs, and is required for receptor recycling. Recently, a connection between endosomal acidification and the Arf6 GTPase/ARNO coat protein factors was identified. Though the precise correlations remain to be determined, Arf6 and ARNO colocalize with vacuolar H^+-ATPase in the apical endosomes of proximal tubules in a pH-dependent manner, a localization that overlaps with that of megalin, Rab5, and Rab11.

12.3 Lysosomal Dysfunction

Numerous diseases occur as a result of lysosomal abnormalities. In fact, mutations causing lysosomal enzyme deficiencies account for approximately 40 different disorders collectively called *Lysosomal Storage Diseases* (*LSDs*). In many cases, lysosomal defects lead to an increase in the size and number of lysosomes, eventually causing malfunction of the affected organ or organs. All LSDs are serious conditions, and most are fatal, resulting in death in infancy or early childhood. Many LSDs are associated with neurodegeneration, and lead to severe clinical manifestations such as mental retardation, progressive cognitive decline, and inappropriate behaviors. Interestingly, these conditions are also phenotypic of common age-related neurological disorders such as Alzheimer's and Parkinson's disease. In fact, it is believed that, since total cellular lysosomal capacity is reduced with brain aging, lysosomal abnormalities may contribute to age-related neuropathogenesis.

12.4 The Cancer Link

The importance of endocytosis in the downregulation of signaling complexes implies, perhaps, obvious connections to cancer. The ErbB family of receptor tyrosine kinases (RTKs) consists of transmembrane receptors including EGFR, Neu/ErbB-2, ErbB-3/HER3, and ErbB-4/HER4. These signaling receptors are involved in epithelial development, renewal, and remodeling, and thus, are major regulators of cell proliferation. c-Cbl is a large, multimodular cytoplasmic protein involved in endocytosis that binds phosphorylated EGFR via an N-terminal tyrosine kinase binding domain. c-Cbl is also an E3 ubiquitin ligase, and ubiquitylates EGFR prior to clathrin-coated pit formation; however, it also colocalizes with EGFR in MVB luminal vesicles. Interestingly, c-Cbl was originally identified as the cellular form (hence the "c") of viral-Cbl (v-Cbl), a transforming protein of the Cas NS-1 retrovirus. v-Cbl contains only the N-terminal region of c-Cbl, which binds to but does not ubiquitylate EGFR; this causes EGFR to be constitutively recycled rather than degraded, and leads to enhanced signaling and oncogenic transformation.

A link to cancer is found in several other endocytic proteins. Chromosomal translocations leading to fusions between three different endocytic proteins and ALL1/HRX-related gene products have been linked to hematopoietic cancers. A fusion between the C-terminal EH domain of AF-1p (the human ortholog of murine Eps15) with the N-terminus of ALL1/HRX

is implicated in two myeloid leukemias. A similar fusion between the N-terminus of ALL1/HRX and the C-terminal domain of SH3p8 (endophilin) occurs in an acute myeloid leukemia. Finally, a fusion containing the full-length CALM protein (ubiquitously expressed AP180 homolog) with its last four amino acids replaced by amino acids 87–1027 of the AF10 gene product (a putative transcription factor) was identified in a lymphoma cell line.

13 Conclusion

The complexity of the endocytic pathway includes requirements for many protein components and numerous membrane compartments, the selection and sorting of cargo that occurs at each step along the pathway, and the intricate regulation of these events that ultimately determines cellular physiology and responses to environmental changes. Many of the lessons learned from molecular cell biological studies of endocytosis also apply to other membrane trafficking pathways, and in fact may foreshadow a greater complexity in these other pathways than was previously appreciated. For example, a similar multiplicity of adaptors and cytosolic factors necessary for the formation of CCVs at the plasma membrane is beginning to be uncovered in studies of CCV formation at the TGN.

In this chapter, we strove to present the current understanding of the molecular mechanisms of endocytosis and to highlight a few of the physiological functions served by these mechanisms; however, there are many important questions that remain controversial and critical breakthroughs that are imminent. Perhaps the most debated area continues to be on the issue of individual compartment identity and whether compartments arise through maturation as opposed to somewhat ''static'' compartments through which cargo moves via vesicular-mediated transport; recent experimental approaches are yielding fresh insight into this fundamental and long-debated question. It may be informative to consider the endocytic pathway analogously to the biosynthetic pathway: endocytic ''hot spots'' could correspond to transitional ER exit sites, EEs to the ER–Golgi intermediate compartment, and LEs may mature from one type into another akin to maturation of sequential Golgi cisternae. In this view, the endocytic pathway would utilize both vesicular transport and maturation mechanisms and might rely upon distinct protein coats that direct forward traffic versus retrieval/recycling pathways.

How flow through the endocytic pathway is regulated is another area with many outstanding questions. This will undoubtedly entail studies of protein kinases and phosphatases, lipid modifying enzymes and enzymes that govern protein ubiquitylation, and perhaps other posttranslational modifications not yet anticipated. To understand fully the roles of these regulatory enzymes will require knowledge of how these factors themselves are regulated and what dictates their subcellular localization and substrate specificity.

A final emerging area of great interest for studies of endocytosis is defining the role(s) for the cytoskeleton, particularly the actin cytoskeleton. Many connections between the cytoplasmic endocytic machinery and actin have been uncovered through biochemical and genetic approaches, but the function of the dynamic polymerization/depolymerization cycle in endocytosis remains elusive. Finding the answers will be complicated by the pleiotropic roles

played by actin, and the way in which cells adapt to perturbations of one specific membrane trafficking step by spilling over into alternate pathways.

Our current understanding of endocytosis has been achieved through a wide variety of experimental approaches, and the field of endocytosis continues to be one in which novel and interdisciplinary approaches to cell biological mechanisms are pioneered. Great advances have been made using the tools of structural biology, beginning with seminal studies describing the clathrin lattice, and we anticipate that the pace with which endocytic mechanisms are elucidated at the atomic level will continue to increase. We also anticipate that exciting advances will continue to emerge as live-cell imaging methods facilitating sophisticated four dimensional (simultaneous spatial and temporal) analyses of endocytic proteins in action in the intact cell are developed and applied, along with *in vitro* reconstitution assays that accurately recapitulate individual stages of endocytosis. These approaches, together with increased use of genetic analyses – including newer methods (such as interfering RNA and tissue-specific homologous recombination) that increase the range of organisms in which detailed genetic studies are possible – will eventually lead us to a full and complete appreciation of the inner workings of endocytosis, in particular, and of membrane trafficking processes in general.

Keywords

Biological Markers (Biomarkers)
Biochemical, molecular, genetic, immunologic, or physiologic signals of events in biological systems.

Biologic Markers of Effect
A measurable cellular, biochemical, or molecular alteration within an organism that, depending on magnitude, can be recognized as an established or potential health impairment or disease.

Biologic Markers of Exposure
A xenobiotic chemical or its metabolite, or the product of an interaction between a chemical, physical, or biologic agent and some target cell or biomolecule.

Biologic Markers of Susceptibility
An inherited or acquired indicator of the response of an individual or a population to a specific xenobiotic agent.

Molecular epidemiology is the use of molecular biological techniques to identify exposures, effects, or susceptibility factors in studies of human populations. Molecular epidemiology and traditional epidemiology utilize the same paradigm. However, the former presents the opportunity to use the enhanced resolving power of molecular biology in the assessment of exposure–disease relationships.

The resolving power, to elucidate a continuum of events between xenobiotic exposure and disease, can provide stronger approaches to research, prevention, and intervention. One particular aspect of the new resolving power of molecular epidemiology is the application of the products of genomic research to epidemiology to assess the genetic components of disease and the interaction between genetic and environmental factors in disease causation. Conversely, the molecular epidemiologic approach may contribute to genomics research by emphasizing the importance of populations and a population perspective. Genetic biomarkers reflect population dynamics and represent useful tools in uncovering complicated interrelationships between environment, culture, and genetics in human history.

1 Principles

The use of molecular biological techniques in epidemiology provides a potentially powerful tool for medical and public health researchers. These techniques allow for the identification of biological markers (Fig. 1) that can indicate exposure to a xenobiotic agent, reveal a biological effect early in the natural history of disease, or represent unique disease subtypes or susceptibility

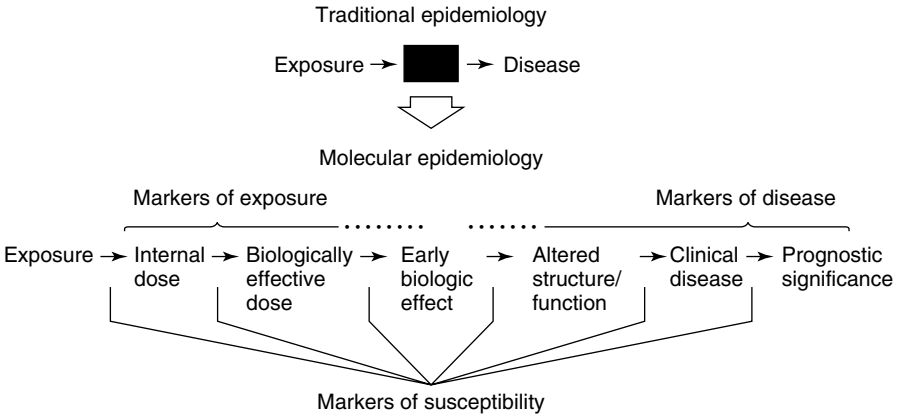

Fig. 1 Enhancement of the traditional epidemiologic paradigm by the use of biological markers resulting in a molecular epidemiologic approach. In traditional epidemiology, the mechanism of action is often a ''black box,'' and associations between an exposure and disease are made by inference. In molecular epidemiology, a continuum between an exposure and a disease is defined, and various markers are identified.

to the development of disease. Although the use of biological markers in epidemiology is not new, the current generation of molecular biological markers enhances past approaches. Epidemiology is an observational science: one makes inferences about disease and health on the basis of comparing groups of people in terms of disease incidence and mortality. Ideally, the groups being compared should be similar in all respects except for the risk factor in question. A benefit of molecular epidemiology is that instead of comparing two groups on the basis of environmental exposure, investigators can compare populations with respect to dose of an environmental agent as measured in critical macromolecules, such as DNA or surrogate proteins for DNA under some conditions, this is presumably a more accurate means of classifying the subjects' true exposure. At the other end of the exposure-disease continuum, instead of using frank disease as an outcome variable in an epidemiologic study, it is possible to use a validated biologic marker of effect.

1.1 Biological Markers of Exposure

The utility of a biological marker of exposure depends, in part, on its half-life, the pattern of the exposure it is measuring (e.g. regular daily exposure vs infrequent episodic exposure), and whether secular trends have occurred in that exposure (e.g. smoking cessation). In addition, the information it provides must be compared with the availability and quality of other sources of data (e.g. questionnaires, environmental monitoring, medical records). Essentially, all exposure measures misclassify some subjects – it is the relative ability of different sources of data to correctly place individuals into exposure categories that must be considered. For example, subjects can generally report average smoking habits and smoking duration in an accurate manner, permitting the calculation of cumulative exposure. Since internal dose markers associated with tobacco smoke have relatively short half-lives, and thus reflect only recent exposure (e.g. cotinine,

a metabolite of nicotine), they have limited utility by themselves to directly assess a smoking–cancer relationship.

In contrast, it is difficult to obtain accurate information about dietary exposure to aflatoxin by using a questionnaire because exposure is sporadic and is present in a spectrum of different food types. In this instance, even a short-term internal dose marker might classify the long-term exposure status of subjects more accurately than questionnaire data. For example, a nested case–control study conducted in Shanghai, China, demonstrated that aflatoxin exposure assessed by measuring several aflatoxin metabolites (and an N_7-guanine aflatoxin adduct) in banked urine samples was associated with an increased risk of hepatocellular carcinoma, while aflatoxin exposure assessed by questionnaire was not associated with elevated risk.

1.2 Biologic Markers of Effect

In terms of disease, techniques are available for identifying biological changes earlier in the continuum between homeostatic response to pathological agents or conditions and development of frank disease. This advance has implications for identifying opportunities for prevention. Biologic markers intermediate between exposure and disease, if validated for disease or risk of disease, can be used to screen people or to allow for early disease detection. These markers can also be used in intervention trials as outcome indicators rather than waiting for subjects to develop disease. There is a popular notion that molecular epidemiology has the potential to contribute to assessment of risk of an individual. However, that point needs clarification. Historically, it has been possible to use an epidemiologic data set, that is, data on a group consisting of sick and healthy people, with and without certain risk factors, to develop risk functions that provide for an estimate of individual risk. This was accomplished in the 1960s using data from the Framingham Longitudinal Study of cardiovascular disease. On the basis of the knowledge of the risk for people with a certain aggregation of characteristics, it was possible to predict the risk for an individual. Molecular epidemiologic approaches provide a means for more confident estimation because more mechanistic information can be utilized. Still, the resultant assessment is only probabilistic determination, not deterministic. While the prediction is that a certain individual is likely to develop disease in the future, there is no guarantee that he or she will develop it. A biomarker may have the utility to screen populations at high risk of disease as part of a primary or secondary prevention effort. However, a substantial amount of information is required before a biomarker can be used for this purpose. In particular, the cumulative probability that an individual will develop disease over a defined period, given a constellation of biologic and nonbiologic risk factors, must be estimated along with a calculation of its uncertainty.

1.3 Biologic Markers of Susceptibility

One of the greatest contributions of molecular epidemiology is the ability to discern the role of host factors, particularly genetic factors, in accounting for variation in response. Why similarly exposed people do not get the same diseases is a target question for molecular epidemiology. In most disease systems, susceptibility markers are being identified and evaluated. These markers can be incorporated

into epidemiologic models as modifiers of the relationship between an exposure and an effect (see Sect. 2.1.3). Traditional epidemiologic approaches can also be enhanced by using molecular genetic techniques to identify host factors that could account for differences in disease risk. Thus, for example, a metabolic polymorphism can be detected from peripheral blood lymphocyte DNA, and groups at potentially greater and lesser risk of disease can be distinguished. The category of markers of susceptibility includes polymorphisms in genes responsible for chemical activation or detoxification, DNA repair, and genomic stability. Susceptibility genes of some types may interact with chemical exposures of very specific types (e.g. cytochrome P450 enzyme subtypes and phase II conjugating enzymes), while others may confer more general susceptibility (e.g. p53 mutations in Li–Fraumeni syndrome). Markers can be measured at the DNA level, if the genetic basis of a polymorphic phenotype has been identified, or at the phenotypic level (e.g. drug probes of hepatic enzyme activity, DNA repair measured in peripheral lymphocytes).

1.4 Utility of Molecular Epidemiology

Molecular epidemiology is a useful temporary blanket term that reflects the reality that increasingly disease, causal exposures, and risk factors are being defined at the molecular level. The utility of this term is that it serves as a signpost for epidemiologists to consider using independent (risk factor) and dependent (outcome) variables that are derived from molecular biological techniques and assays. So, for example, DNA adducts may be used in addition to breathing-zone measurement of a carcinogen, gene mutational patterns may be used as an indicator of disease rather than a nosological death certificate, and genotyping based on the polymerase chain reaction can be used in addition to race and sex to stratify populations for comparisons. In summary, molecular epidemiology has the potential to contribute the following opportunities and capabilities to public health:

- Delineation of a continuum of events between an exposure and a resultant disease
- Identification of exposures to smaller amounts of xenobiotics and enhanced dose reconstruction
- Identification of events earlier in the natural history of clinical diseases and on a smaller scale
- Reduction of misclassification of dependent and independent variables
- Indication of mechanisms by which an exposure and a disease are related
- Better accounting for variability and effect modification
- Enhanced individual and group risk assessments

2 Techniques

If molecular biological markers in epidemiology and public health can be used in the ways described in Sect. 1, they must be demonstrated to be valid in terms of both the assay and the marker. An assay will be valid if it measures what it is expected to measure. A marker will be valid for epidemiologic purposes in two ways. First, it will be valid to the extent that it represents exposure, disease, or susceptibility. Second, it will be valid insofar as the extent of variation in groups with different demographic, behavioral, or medical characteristics is known. A key question

is the prevalence of a particular biomarker (e.g. a mutation) in different ethnic or racial groups, in smokers or drinkers, or in people with various hereditary and acquired diseases. Molecular epidemiologic approaches can be useful in the validation of molecular biological markers in these two ways.

2.1 Representational Validity of Molecular Biological Markers

2.1.1 Validation of the Relationship between Exposure and Dose

Exposure → Internal dose

→ Biologically effective dose

Molecular markers of exposure may be validated by assessing the relation of an exogenous exposure to an internal dose or a biologically effective dose. Critical in validation studies is the need to have an effective exposure assessment. It may be necessary to use a combination of personal and environmental monitoring and questionnaires, record review, and modeling to reconstruct exposure history. The approach also requires an understanding of the pharmacokinetics associated with the particular xenobiotics. Related to this is the need to understand the natural history of the marker and to use it in the validation study. For example, in a study of hydroxyethyl hemoglobin adducts in workers exposed to ethylene oxide, the life span of the erythrocyte, hence the constituent hemoglobin molecule (~4 months), was used as a dosimeter of cumulative exposure. There is also a need to account for factors that might influence the appearance of a molecular biological marker. In the aforementioned studies, when mean values were adjusted for important covariants such as age, cigarette smoking, and education, an exposure–response relationship was found at levels below the permissible exposure level.

2.1.2 Validation of the Relationship between Biological Effects and Disease

Early biologic effect → Altered structure/

function → Clinical disease

Validation information in the biological effects–disease category is limited. The often-repeated question is, "What do the data concerning health and disease mean?" Validation studies of these types are difficult to accomplish because of the temporal factor. Identification of an early effect – that is, an effect in pathogenesis or an effect predictive of disease – generally requires a prospective study design, although cross-sectional clinical studies of diseased and heavily exposed individuals can be used to great advantage. When a prospective design is not used, however, care must be taken to avoid biased associations. This is often difficult; hence prospective studies are the best approach for validation. Prospective studies are expensive and time-consuming, and few are conducted. For example, despite the large number of studies on most of the cytogenetic markers, there is little consensus on their predictive value because most of the studies have been cross-sectional and markers were not linked to disease. Specifically, in epidemiologic terms, predictive value is evaluated in terms of the percentage of those who test positive for a marker and actually develop the disease. Performing the appropriate prospective studies of sister-chromatid exchanges would take a large population and a relatively long time. The best example of such a study is the Nordic prospective study on the relationship between

peripheral lymphocyte chromosome damage and cancer morbidity in occupational groups. Ten laboratories in four Nordic countries participated in a study of a combined cohort of persons (mostly from occupational groups) who had been cytogenetically tested. The cohort is being followed prospectively for cancer morbidity. The cohort comprises 3190 subjects, of whom 1986 subjects (62%) have been scored for chromosome aberrations and 2024 subjects (63%) scored for sister-chromatid exchanges. Preliminary analysis indicates that chromosomal aberrations are associated with cancer. These biologic markers in peripheral lymphocytes represent carcinogenic changes elsewhere in the body. This is the critical criterion of a useful biologic marker. To serve as a valid outcome measure, an intermediate marker must be correlated with disease risk. The criteria for validating intermediate biomarkers have been extensively discussed and include the sensitivity of the marker (i.e. the proportion of subjects who develop cancer and who are positive for the biomarker), the relative risk (a measure of the strength) of the association between the marker and disease, and a judgment about the extent to which the exposure–disease relationship is mediated through a process reflected directly or indirectly by the marker.

2.1.3 **Validation of Markers of Susceptibility**

Exposure → Susceptibility → Disease

The tools of molecular biology and analytical chemistry have allowed researchers to identify a degree of interindividual variability not previously imagined. Validated biological markers of susceptibility can serve as effect modifiers in epidemiologic studies. Effect modification is a term with statistical and biological aspects. Statistically, the examination of the joint effects of two or more reactors is often discussed in the context of effect modification. It depends on the statistical method (e.g. multiplicative or additive) used to model interaction. From the biological perspective, effect modification contributes to answering the question of why all similarly exposed individuals do not develop a disease. The answer, in part, lies in individual variability in metabolic and detoxification capabilities, their ability to repair genetic damage, or other host factors.

To validate a susceptibility marker, it is important to minimize misclassification, which can occur as a result of laboratory or epidemiologic factors that affect phenotyping or genotyping. Next, it is necessary to demonstrate that the marker increases the risk of disease. The issue of the correlation of acetylation phenotype and bladder cancer from aromatic amines illustrates the concept of susceptibility. Some aromatic amines are detoxified by the enzyme *N*-acetyltransferase, and the slow phenotype of this enzyme has been associated with bladder cancer in exposed individuals. Despite a plethora of studies, the scientific literature is not conclusive on the extent to which being a slow acetylator modifies the risk for bladder cancer in people exposed to aromatic amines. Generally, most studies have been too small, have had weak exposure characterization, and were not designed to allow proper determination of whether exposure or susceptibility was the key factor. An example of how partial validation of a susceptibility marker might occur without using disease as the outcome involved the formation of hemoglobin adducts (which are documented surrogates for DNA adducts

believed to be involved in carcinogenesis) in slow and fast acetylators who had been exposed to 4-aminobiphenyl. Slow acetylators had an average of 1.5-fold greater frequency of adducts than the fast acetylators. Despite these encouraging efforts at validation, few markers of susceptibility have been validated and none are ready for use in population screening.

2.2 Validation of the Behavior of Molecular Biological Markers

Before biomarkers can be used for etiological and prevention research, they need to be validated in populations. This calls for the development of analytical methods for use in large-scale populations. Currently, there is inadequate research support for scaling-up efforts needed for population studies. The validation and scaling efforts discussed here require close collaboration between laboratory scientists and population scientists (clinicians, epidemiologists, industrial hygienists, and exposure assessors). Transitional studies bridge the gap between the development of molecular markers in the laboratory and their application in population-based studies. These studies generally involve the initial evaluation and application of biomarkers in healthy human populations. Their objective is to address issues in sample processing, evaluate assay accuracy and precision, collect information about potential confounders and effect modifiers, and study early biologic effects of selected exposure. Transitional studies can be divided into three broad categories to clarify their distinctive research goals: developmental, characterization, and applied studies. In practice, however, elements of all three types of study are often incorporated into a single field investigation.

2.2.1 Developmental/Characterization Studies

Identification of a promising new molecular biomarker in the laboratory does not mean that the biomarker is ready for use in an epidemiologic study. Other basic issues need to be resolved before its application in human studies can be considered. First, the reliability (i.e. the repeatability of the assay) of a marker must be determined. As long as an assay is reliable, the ordering of subjects by the measure is preserved. Since this is all that is required for studying a marker–disease relationship, reliability, and not accuracy, is of initial importance. Reliability of laboratory assays may be assessed by the analysis of blind replicate samples representative of the range of values likely to be found in human populations. After the assay reliability and accuracy has been determined, it is important to define the optimal conditions for collecting, processing, and storing biological specimens for eventual assay, since, not uncommonly, small variations in these conditions determine the subsequent analyzability of samples. These studies are generally designed to address questions about the presence or the levels of a newly developed marker in the general population. In addition, they serve to identify factors that are confounders or effect modifiers of a marker (e.g. age, gender, medications) that need to be measured and taken into account when applying the marker in subsequent studies.

2.2.2 Applied Studies

Applied studies are investigations performed on subjects with particular patterns of exposure to xenobiotics (e.g.

occupational exposures, smokers) or on patients receiving chemotherapy. In these studies, the biomarker is treated as the outcome variable. At this stage of research, the biomarker has not been shown to predict an increase in risk of disease. The marker, however, can often be used to provide insight into the association between external exposure and biologic processes early in the exposure–disease relationship. Applied studies can help establish the biologic plausibility of associations detected in etiologic studies. Applied studies generally cannot establish a causal relationship between a given exposure, or a given level of exposure, and the risk for developing disease. The results of applied studies using the biomarker as outcome are suggestive only until a marker is shown to predict disease risk, which can be established only by comparing risk of disease in individuals with and without the marker. In these studies, the biomarker may be overly sensitive (i.e. it may respond to low levels of chemical exposures without biological relevance), it may be insensitive, or it may reflect phenomena that are irrelevant to the disease process. Until these relationships have been sorted out, the findings are merely suggestive.

2.3 Etiologic Studies

The major objective of molecular epidemiology is to conduct etiologic and applied research. Etiologic studies [i.e. ecologic, case–control, case–case (also referred to as a case series), prospective cohort, family, twin, and intervention studies] can be distinguished from transitional studies in that the former involve either clinically ill subjects, asymptomatic subjects with early disease, or subjects positive for an intermediate process known to be associated with increased risk of disease (e.g. colon adenomas and risk of colon cancer). Case–control, case–case, and prospective etiologic studies can effectively utilize molecular epidemiologic approaches.

2.3.1 Case–control Studies

A case–control study involves the comparison of cases (people with a particular disease) with controls (people without that disease) for various risk factors. The risk factors could be an exposure, a trait, or a biomarker. Traditionally, case–control studies have involved patients with clinically confirmed disease, identified either through the presence of symptoms or as a result of incidental findings on routine clinical examinations. Increasingly, cases are being defined as asymptomatic subjects whose early preclinical disease has been ascertained by screening (e.g. early breast disease, colon polyps, cervical dysplasia). The case–control study design is used far more frequently than the prospective cohort study design because of its relatively greater efficiency and lower cost. Therefore, maximizing opportunities to creatively integrate biomarkers into case–control studies is important. Because some markers are affected by disease itself, which raises complications of reverse causality, it is important to define which biomarker categories can most effectively be used in this study design.

2.3.2 Case–case Studies

A case–case study involves a series of cases of the same type that are compared on the basis of a particular exposure and a particular biologic characteristic. The accumulation of a spectrum of *ras* oncogene mutations in leukemia cases with benzene exposure compared with those in

leukemia cases without benzene exposure is an example of a case–case study. Such studies have the potential of identifying an exposure-specific effect at the molecular level. Case–case studies, however, cannot be used to estimate the relative risk of disease from a specific exposure. A nondisease control group is required for this purpose. Case–case studies offer great precision in investigating gene–environment interactions when the disease outcome of interest is rare.

2.3.3 Prospective Cohort Studies

Prospective studies involve healthy people, characterized by the presence or the absence of a risk factor, who are followed forward to determine the risk of disease. In prospective studies, the biological samples may be collected from subjects at various times. These samples are either analyzed at the time of collection or banked for later analysis. One way to utilize biologic markers in a prospective study is to follow the groups of subjects forward in time: subjects who develop disease are identified, and premorbid biomarker levels in the group with disease are compared with those without disease. Often, a nested case–control approach is used. Samples from cases and only a sample of the controls (noncases) are analyzed, which considerably reduces the laboratory requirements and costs. Although the prospective study design is by far the most time-consuming and expensive type of observational epidemiologic study, it is the only method available to test the association of biomarkers with disease risk when the markers are transient or may be directly or indirectly affected by disease. Prospective studies may yield banks of biological specimens that are useful for future studies. Large cohort studies initiated in the 1980s and 1990s are, in general, banking most or all fractions of the peripheral blood sample to allow a far wider range of biologic assays to be performed, particularly those that require DNA.

2.4 Molecular Epidemiology and Genomics

Molecular epidemiology and genomics utilize the products of genomic research to identify variation in any gene considered relevant to disease as well as the ''genome-wide'' genotype for every participant in a study. Additionally, products of genomics research will allow classification of diseases in new ways, possibly leading to new interventions. Evaluation of gene–environment interaction is becoming an increasingly important topic that will be complicated by large numbers of gene–gene and gene–environment interaction candidates. Larger-sized study populations (in thousands) will be required to study more than a few genes and environment factors.

Molecular epidemiology can contribute to addressing the issue of massive amounts of data that result from genomics research. The reduction, summarization, analysis, and interpretation of data from a population perspective are necessary to distinguish homeostatic profiles from pathologic profiles. Molecularly defined subsets may be the bases for new classification or definitions of disease.

2.5 Public Health Applications

Public health practice incorporates the end use of validated biomarkers for risk assessment by government agencies, for population screening (both active and

passive), and for clinical and preventive medical practice. The use of molecular biomarkers in public health practice is still in its infancy, although several very promising markers may soon find their way into the public health arena. The standard principles of biological monitoring and medical screening are applicable to the use of any biomarker, however. These include assay reliability and cost, strength of the association between a marker and disease risk, prevalence of the marker in the population, availability of effective, preventive strategies that can be employed in subjects who are positive for the marker, and a host of ethical considerations, such as informing subjects of test results.

Keywords

Epigenetics: epi- Gr.
On or above; in addition to; near; or after. The patterns of inheritance that are not produced by changes in DNA sequence or follow the Laws of Mendel. Most actively studied in the context of DNA methylation and histone posttranslational modifications.

Histones
A family of related basic proteins consisting of H1, H2A, H2B, H3, and H4 and several variants that are organized to provide essential scaffolding for DNA. Histones undergo a variety of posttranslational modifications including acetylation, methylation, phosphorylation, and ubiquitination all of which may influence chromatin structure and function.

Nucleosome
Approximately 146 bases of DNA are wrapped 1.8 times around a core octamer that is formed from a tetramer of histones H3 and H4, and two dimers of histones H2A and H2B. The histone H1 is bound to DNA in between each nucleosome and functions to further compact the nucleosomes into higher ordered chromatin structure.

Euchromatin
The gene-rich region of genomes characterized by more open chromatin structure, gene transcription, and poor staining with basic dyes.

Heterochromatin
The gene-poor region of the genome characterized by dense chromatin structure, little gene transcription, and strong staining with basic dyes.

Loss of Heterozygosity
LOH: A genetic event caused by nonhomologous recombination in diploid genomes resulting in three possible outcomes; (1) the structural deletion of a normal allele or loss of the chromosome carrying a normal allele; (2) mitotic recombination between a normal and mutant allele resulting in the formation of a daughter cell homozygous for deleted or inactivated allele; or (3) duplication of chromosome with deleted or inactivated allele accompanied by the loss of the normal chromosome.

There is convincing evidence that tumorigenesis results from mutations in DNA that lead to critical changes in cell metabolism and are inherited as a cell divides itself. However, the process of tumorigenesis can also be strongly influenced by epigenetic factors. Epigenetic inheritance is defined as inheritance that does not follow normal Mendelian patterns and may involve nuclear components in addition to DNA. We now have significant information about the molecular mechanisms that influence epigenetic inheritance. Most of these mechanisms include direct modifications of either DNA itself or the collection of proteins, called *histones*, which intimately associate with DNA. Unlike DNA mutations, epigenetic events are often reversible, making them exciting new targets for therapy. This understanding is leading to the development of specific drugs that target epigenetic events and thus may complement existing cancer treatments.

1 Introduction: The Chromatin–Cancer Connection

The formation of clonally expanding tumors in multicellular organisms is due to complex changes in cellular physiology, which results in failure of cell-growth control. In 1971 it was hypothesized that two molecular events are required to predispose a cell type to become tumorigenic. Since then, our understanding of tumor-related molecular events has expanded tremendously owing to the advent of molecular biology techniques to clone and functionally characterize individual genes. This collective work has broadly defined genes related to tumor formation into two major classes: protooncogenes that stimulate proliferation and inhibit terminal differentiation and tumor suppressor genes that tend to inhibit proliferation and promote terminal differentiation. The classical two-hit hypothesis affecting a tumor suppressor gene is diagrammed in Fig. 1(a). In this scenario, a mutation occurs that inactivates one allele of the tumor suppressor gene leaving only one fully functional allele. If there is a growth advantage from losing the other allele, most often loss of heterozygosity (LOH) occurs leaving only one nonfunctioning allele in the tumor cell.

It is very clear, however, that mutation is but one way to effectively influence gene expression. Aberrant changes in the local chromatin structure surrounding start-sites of expressed genes can also dramatically alter expression levels and patterns. Interestingly, in tumors this so-called ''epigenetic'' influence on gene expression is also inherited in daughter cells of clonally expanding tumors even when no mutation can be detected. Several mechanisms through which the cell machinery generates epigenetic ''marks'' that communicate structural changes in the chromatin architecture are now becoming clear. The best characterized is the methylation of DNA at cytosine residues located in the context of CpG dyads found in expression control regions. However, more recent research has focused on histone modifications as a part of a ''code'' that communicates to chromatin remodeling factors, thereby affecting rates and levels of transcriptional activation. Indeed, emerging evidence suggests that changes in histone modifications may precede or even trigger DNA methylation. While not yet proven to be heritable,

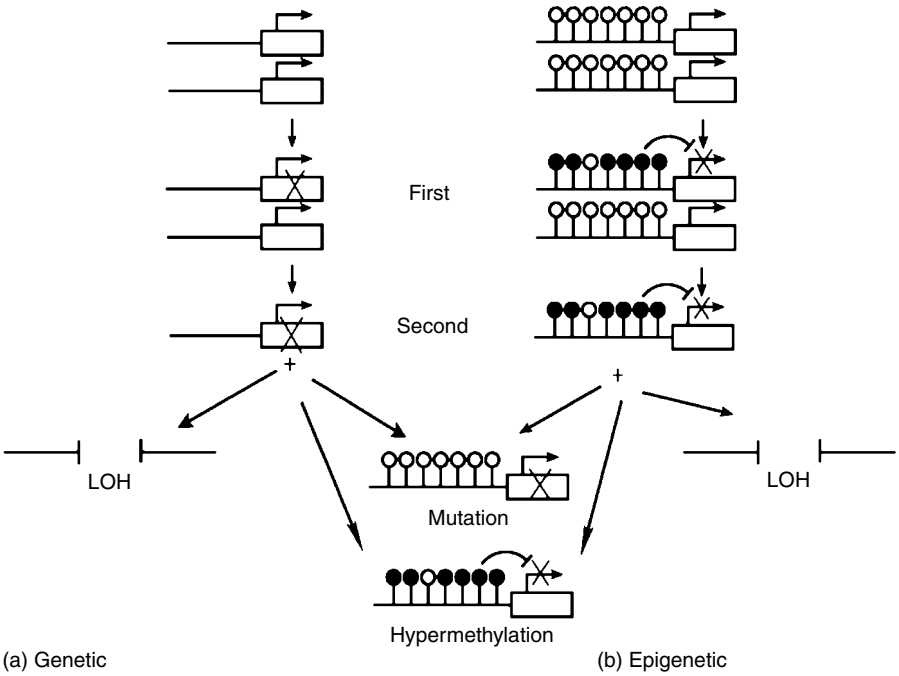

Fig. 1 Genetic and epigenetic two-hit models as the means of silencing a tumor suppressor allele. (a) Classical genetic model of the two-hit hypothesis at a tumor suppressor allele. First hit involves a genetic mutation (marked with an X) of one allele resulting in a single functional allele. Second hit may be the loss of heterozygosity (LOH) or mutation of the second allele resulting in complete loss-of-function protein. (b) Epigenetic model of the two-hit hypothesis at a tumor suppressor allele. The CpG island within the promoter region is unmethylated (○) allowing expression. The first hit results from methylation (●) of CpGs in one allele abrogating its expression leaving only one allele making functional protein. The second hit can be mutation of the unmethylated allele (left), methylation of the second allele (center), or LOH (right).

linkage of histone modifications to DNA methylation renders both to be important in the epigenetic inheritance.

A greater understanding of the importance of epigenetic events in gene expression has allowed a reinterpretation of the two-hit hypothesis to include aberrant epigenetic marks functioning as one or both of the hits. Thus, as diagrammed in Fig. 1(b), a scenario arises in which an epigenetic mark, in this case DNA methylation at a tumor suppressor promoter, silences expression of one allele of a tumor suppressor gene without altering its primary sequence. Again, if there is selective growth advantage by this process, LOH, mutation, or additional hypermethylation occurs at the other allele. Therefore, tumorigenesis can result from any number of combinations of genetic and epigenetic alterations, many of which are discussed below. Because epigenetic marks are often reversible, and most often an epigenetically silenced allele does not also harbor mutations, they are exciting new targets for tumor therapy strategies aimed at reactivating silenced tumor suppressors.

An increasing number of loci that are important in cancer are being determined to be inactivated both by mutation and by silencing through epigenetic means. The focus of this chapter is to outline current knowledge of epigenetic influences on gene expression and the role of these modifications in tumor formation. We will discuss in depth the role of DNA methylation and chromatin modifications in tumor formation and progression; however, we will also briefly discuss another epigenetic modifier of gene expression brought about through RNA-mediated silencing. We first discuss the mechanisms of generating and maintaining epigenetic marks followed by the evidence that epigenetics is intimately linked to tumorigenesis. Finally, we discuss how epigenetic marks can be detected in tumor cells, and current and potential therapies that are directed at cancers influenced by epigenetic events.

2 Epigenetic Modifiers

Epigenetic regulation of gene transcription occurs in at least three layers of the structural hierarchy of the genome. They are on DNA itself, through DNA methylation; at the level of the nucleosome, through histone modifications; and at the level of the chromosome, through chromatin binding structural and remodeling proteins. These ''marks'' and the proteins responsible for making them can influence gene expression on a global level by compacting or relaxing large segments of the genome or on the local level as coactivators and repressors of inducible gene expression. The formation of these epigenetic marks is enzyme-dependent and is highly regulated. Table 1 notes broadly the types of modifications that occur on DNA, and the individual histone proteins, and the types of cellular enzymes that catalyze the process. Following is a discussion of those processes that play known roles in tumor formation.

2.1 DNA Methylation

The 5′ carbon of cytosines that are found in the context of the CpG or CpNpG nucleotide sequences throughout the genome can be methylated. This produces 5-methylcytosine, often referred to as the *fifth base*. The methylation of DNA has

Tab. 1 Types of epigenetic modifications in chromatin.

Substrate	*Epigenetic marks*	*Residue target*	*Chromatin target*	*Enzyme types*
DNA	Methylation	Cytosines in CpG dyads	DNA	DNA methyltransferase (DNMT)
Histones	Methylation	Lysine and arginine	H3, H4	Histone methyltransferase (HMT)
	Acetylation	Lysine	H3, H4, H2A, H2B	Histone acetyltransferase (HAT)
	Phosphorylation	Serine and threonine	H3, H4, H1	Kinase
	Ubiquitination	Lysine	H2A, H2B	Ubiquitin ligase

been shown to serve at least two major purposes. First, it serves as something akin to a genetic immune system targeting foreign DNAs such as viruses that become incorporated into the genome nonhomologously and silencing their expression. Second, because methylation occurs postreplication, it may serve to mark the parental strand in replication and direct DNA excision repair enzymes to recognize the base in a mismatch that is incorrect. A more recently uncovered role for DNA methylation is a direct influence on both temporal and spatial control of gene expression. It is estimated that 60 to 90% of the CpG dinucleotides in the genome are methylated. The promoters of many highly expressed genes contain CpG islands, where many copies of the CpG dinucleotide are found in a relatively small area near the transcriptional start site. Unlike most genomic CpGs, the CpGs within these islands are mostly nonmethylated.

Normal DNA-methylation patterns are established during embryonic development. DNA in the ovary and sperm is highly methylated. Upon fertilization, the zygotic DNA undergoes rapid demethylation and new methylation patterns are subsequently established near implantation. These patterns continue to be altered throughout differentiation and development. A hallmark of the tumor genome is a decrease in overall DNA methylation. Because DNA methylation is so often associated with repression, this decrease was initially thought to result in aberrant upregulation of viral and somatic protooncogenes or embryonic alleles normally silenced. However, concomitant with this decrease in global methylation is an increase in localized methylation at certain promoter-associated CpG islands. Thus, gene promoters not normally methylated, become methylated and silenced in many tumors. The differentially methylated regions of the genome also occur in coding regions and other intronic regions of genes that can also correlate to expression changes of those genes.

Unlike mutations that are static and irreversible, DNA-methylation patterns are heterogeneous and dynamic throughout tumor formation and growth. Some evidence suggests that methylation spreads to CpG islands as DNA replicates and that the degree of gene silencing is therefore progressive as a tumor ages. The juxtaposition of euchromatic DNA to heterochromatic DNA is maintained by strict boundary elements to prevent spreading of one conformation into the domain of the other. In some cases, specific proteins that bind to these boundary elements to act as barriers are methylation-sensitive. In normal cells, unmethylated CpG islands in euchromatin are often found in the context of less-CpG-dense DNA regions that are highly methylated and compacted. During tumor formation, methylation of CpGs slowly advances into CpG islands from the surrounding compacted chromatin. Recent evidence indicates that specific histone modifications such as acetylation and methylation may differentially mark the regions; however, much remains to be determined regarding the mechanisms that maintain this separation.

Methylation of CpGs occurs by either *de novo* methylation, where unmethylated CpGs become methylated, or by maintenance methylation in newly replicated DNA, where methylation patterns on the parental strand is recognized as a signal to similarly methylate the newly formed daughter strand. Both types of methylation, *de novo* and maintenance, are catalyzed by a group of proteins called *DNA methyltransferases* (DNMTs). The first of

these to be cloned, DNMT1 is more important in maintenance, methylation having preference for hemimethylated DNA as a substrate. Indeed, DNMT1 is recruited to the hemimethylated template within replication forks implicating its role in reading methylation patterns in parent DNA and copying these patterns to the newly formed daughter DNA strand. That DNMT1 is not required for *de novo* methylation came from introducing proviral DNA sequences into cells that lack DNMT1. These sequences were rapidly methylated similar to wild-type cells and was the first proof that additional DNMTs existed. Subsequently, *DNMT2, DNMT3a*, and *DNMT3b* genes were cloned by virtue of sequence homology to *DNMT1*. *In vitro* analysis indicated that DNMT3a and 3b proteins preferred unmethylated DNA as a substrate, suggesting these may be critical for the *de novo* DNA-methylation activity seen in *DNMT1*-null cells. Humans having specific mutations in *DNMT3b* have a syndrome known as *immunodeficiency centromeric instability and facial anomalies* (ICF). At the DNA level, this disease is characterized by decreases in methylation at pericentric chromatin. The fourth family member DNMT2, while having significant homology to the other DNMTs has no known role in DNA methylation.

While the exact role of DNMTs in human tumor formation is unclear, several clues can be derived from analysis of animal models generated that lack various DNMTs. There are a total of five reported *DNMT1* mutant alleles in mice generated in different laboratories by gene targeting. Most of these that were completely or nearly completely deficient in DNMT1 activity died in early embryogenesis. However, one of these was only moderately deficient in DNMT1 function and mice were viable as a homozygous adult. This particular animal yielded significant insight into the role of methylation in tumor susceptibility when used in crosses to mice with mutations in alleles that are targets for tumor specific methylation (see Sect. 3).

Animal models generated to lack either DNMT3a or DNMT3b also result in inviable animals, although death occurs at different life stages. *DNMT3a* null animals survive embryogenesis, but are growth-stunted during the postnatal period and most die by about four weeks of age. *DNMT3b* null animals do not survive embryogenesis and die between E9.5 and E16.5 of multiple developmental defects. Embryonic stem (ES) cells derived from these animals lacking either DNMT3a or 3b revealed no significant differences in *de novo* methylation targeted at proviral sequence. However, when both were absent, no methylation of these sequences occurred despite expression of normal levels of DNMT1. Finally, ES cells specifically lacking DNMT3b also are hypomethylated at centromeric repeat sequences. It is important to note that these results do not rule out the role of DNMT1 in de novo methylation and also do not rule out the role of DNMT3s or other as-yet-unknown DNMTs in maintenance methylation.

There are several proposed ways in which DNA methylation can lead to gene repression or silencing (Fig. 2). One occurs when the methylated cytosine blocks recognition of DNA sequence by sequence-dependent transcriptional factors (Fig. 2(b)). For example, it has been shown that a differentially methylated CpG in the breast cancer associated-1 (*BRCA1*) gene promoter can prevent binding of a critical transcription factor necessary for full *BRCA1* gene activation. Alternatively, proteins with methyl-CpG binding domains (MBDs) specifically recognize and

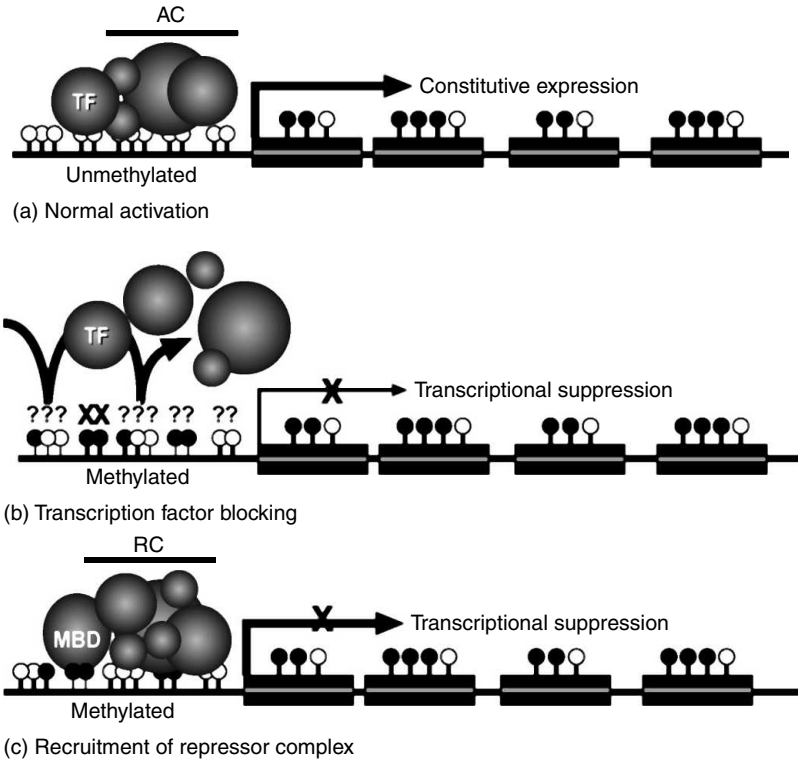

Fig. 2 Potential mechanisms of DNA methylation-induced silencing. (a) Normal transcriptional activation occurs when transcription factors (TF) bind to specific unmethylated (○) sequences in DNA and recruit transcriptional activation complexes (AC) to permit constitutive or inducible gene expression. (b) Methylation causes blocking of TF binding. Aberrant methylation (●) at select CpGs within the same region in tumor subclones (as indicated by XX at the TF binding site) alters the binding of TF and subsequent failure to recruit the AC to the promoter. (c) Aberrant methylation at select CpGs causes recruitment of a methyl binding domain protein (MBD) which then recruits a repression complex (RC) to the promoter inhibiting transcription.

bind to methylated Cs (Fig. 2(c)). Proteins identified that have MBDs include MeCp1, MeCp2, and MBD1, 2, 3, and 4. MeCp1 and 2 also contain transcriptional repression domains that recruit repression complexes (RC) such as Sin3 and Mi-2/NuRD that in turn recruit histone deacetylases (HDACs). These complexes also contain members of the SWI/SNF complexes that may serve to reposition nucleosomes into repressive conformations (see Sect. 2.2). The failure of any one of these complex recruitment pathways could alter the transcriptional context of a significant fraction of the genome.

Methylation of CpGs in certain contexts may lead to mutation in coding regions of genes. The spontaneous deamination of 5-methylcytosine changes the base to a thymine and in the absence of DNA repair causes a heritable sequence change. This accounts for the

significant underrepresentation of CpGs in the context of dinucleotides in mammalian genomes. Occurrence of this change in coding regions of genes can lead to amino acid changes and often truncations. For example, nearly half of all mutations that occur in *p53* in conjunction with tumor formation occur at or are near methylated cytosines within the coding region. Methylations of CpGs within *p53* are the basis for its increased mutation rate when exposed to UV light due to methylation-based changes in the UV absorption spectrum. Furthermore, G to T transversions in *p53* caused by certain carcinogens are more common when Gs are next to a methylated C. Thus, it can be postulated that genes that contain methylated CpGs within their coding regions are potentially more susceptible to mutations caused by environmental factors such as UV light and carcinogens.

Another environmental factor, nutrition, plays a significant role in DNA methylation. Low levels of folate and choline in diet are associated with global DNA hypomethylation and liver cancer in rats. Furthermore, higher folate intake in humans is associated with lower levels of colon cancer and smoking-related lung cancer. One of the potential connections of folate-to-cancer incidence is dependence on folate and folate metabolites to maintain a cellular balance of *S*-adenosyl methionine (SAM), a cofactor for methyltransferases. DNMTs use SAM as a methyl donor group in its enzymatic reaction. Dietary methionine and choline are the building blocks for SAM synthesis and folate functions to prevent accumulation of *S*-adenosyl homocysteine (SAH), the demethylated form of SAM and a potent methyltransferase inhibitor. In the absence of dietary methionine, methionine can be generated from homocysteine using methyl groups derived from either folate or choline. The effect of global changes in the SAM/SAH ratio impacts levels of DNA, RNA, and protein methylation.

2.2 Chromatin Architecture and Modifications

Before discussion on how chromatin is modified to affect gene expression and tumor formation, it is necessary to describe the nature of chromatin itself. In eukaryotes, DNA is compacted into a higher order chromatin structure by association with the family of highly conserved histone proteins. The fundamental unit of chromatin is the nucleosome consisting of ~146 bases of DNA wrapped 1.75 turns around an octomer of histone proteins. The octomer itself consists of two H2A/H2B dimers, and an H3/H4 tetramer that form a tight spool-like structure as determined by NMR and crystallographic studies (Fig. 3(a)). Each nucleosome is linked to the next via a variable length of DNA to which the linker histone H1 is bound (Fig. 3(b)). This histone is thought to be critical for the folding of the chromatin fiber and establishment of the higher order structure. Each of the core histone proteins consists of a globular domain and a tail. The position of the tail domains could not be assigned in nucleosome crystallographic studies, implying that the tail domains do not form an ordered structure. While the minor groove of the double helical DNA faces the nucleosome core, it is thought that these tails may protrude into the major groove of the helical DNA, the surface involved in most protein–DNA interactions. These interactions, influenced by the type and position of modifications of the histone tails, form the basis of the ''histone code'' hypothesis.

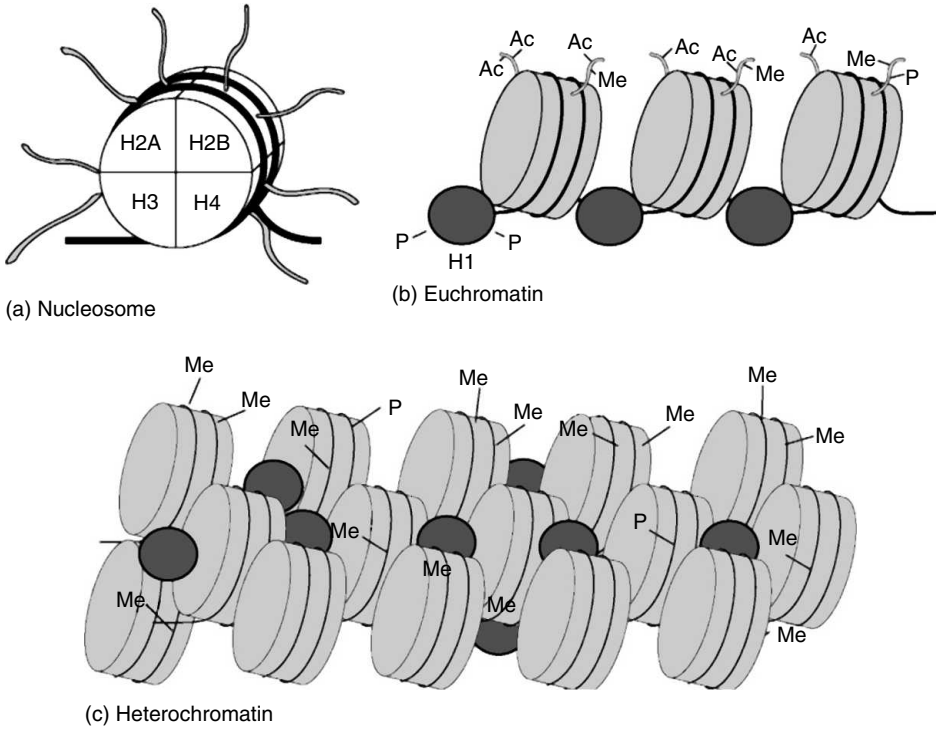

Fig. 3 Chromatin structure and modifications. (a) The nucleosome core particle structure consists of four subunit histones H3, H4, H2A, and H2B. DNA (bold lines) is wrapped around an octomer of these histones approximately twice. Histone tail domains are shown to protrude from the nucleosome and are available for protein–protein interactions with transcriptional and chromatin regulators. (b) Euchromatic DNA forms an open conformation available for binding of transcription factors. Histones in these regions are most often acetylated (Ac), but also methylated (Me) at certain positions. Histone H1, the linker histone, resides in regions of DNA between nucleosomes. H1 makes contact with each nucleosome and may also form protein–protein interactions with transcriptional and chromatin regulators. H1 can be phosphorylated (P) at multiple residues. (c) Heterochromatin forms a closed conformation inhibiting access of transcriptional regulators to DNA. Histones in heterochromatin are most often methylated (Me). DNA methylation is also increased in heterochromatin.

Chromatin structure may be viewed as being organized into two functional modules called *heterochromatin* and *euchromatin*. DNA, modeled into heterochromatin, represents the majority of the genome and consists mainly of repetitive DNA sequences, centromeric, and telomeric chromosome regions, and also includes genes that are differentially expressed depending on any number of other factors. The chromatin structure in heterochromatin is tightly compacted and densely associated with nucleosomes and histone H1 (Fig. 2(c)). The formation of heterochromatin, broadly speaking, prevents expression of unwanted proteins and is heterogeneous from one cell-population to the next. Actively transcribed

or ready-to-be transcribed genes reside in euchromatin. The structure of euchromatin is not compacted, and has fewer nucleosomes that are phased or unevenly spaced to allow a permissive environment for transcription factor binding and transcriptional initiation (Fig. 2(b)). Nucleosomes in euchromatin are more highly acetylated than in heterochromatin. Boundary elements in chromosomes have been found to separate heterochromatin from euchromatin implying that heterochromatin has the potential to spread. Typically, if a normally euchromatic, actively expressed gene is transposed to a region of heterochromatin, the gene will adopt a heterochromatin formation and become silenced.

While heterochromatin is a relatively stable structure, highly methylated and compacted, the structure of euchromatin is constantly being remodeled in response to cellular signaling. Factors that influence this remodeling fall into two classes. The first of these includes a number of large multiprotein chromatin remodeling complexes, the most well characterized being the SWI/SNF complexes; the name derived according to homology with similarly functioning yeast proteins. These complexes regulate accessibility of DNA within nucleosomes to transcription factors by loosening or tightening DNA–histone contacts and shifting histone octomers along DNA. The SWI/SNF complexes can interact with both transcriptional repressors and activators; however, the specificity of such interactions and their role in tumor formation is only just becoming clear. At the core of these complexes is an ATP-dependent DNA helicase that is essential for remodeling activity. In mammals, there are two main remodeling complexes that contain one of two ATP-dependent helicases called Brahma (*Brm*) and Brahma-related-gene-1 (*Brg1*). Both *Brg1* and *Brm* may participate in growth control via interactions with either Rb or BRCA1, as has been demonstrated in tumor cell lines. Moreover, mice deficient for one allele of *Brg1* have increased incidence of leukemia. Furthermore, a component of the SWI/SNF complex called SNF5 is linked to rhabdoid tumors in humans and animal models, a rare but highly aggressive pediatric tumor condition affecting brain, liver, and kidney tissues.

The second class of chromatin modifiers includes proteins that recognize and covalently modify histone tails within nucleosomes. The fact that histones are modified by acetylation, methylation, phosphorylation, and ubiquitination has been known for decades. However, the discovery that histone-modifying enzymes are critical players in the activation of transcription highlighted the dynamic role of histones in the regulation of gene expression. Further insight into these roles of histones in chromatin metabolism came with the advent of immunochemicals that allow visualization of modified histones within the chromatin context. This work has revealed that histones in euchromatin display a distinct range of histone modifications from the ones located in heterochromatin. More important is the yet emerging role of histone modifications in heterochromatin assembly and maintenance of DNA methylation; two events strongly linked to tumorigenesis. The location of most modified residues in the core histones and the linker histone H1 are known (Fig. 4). However, the function of each in modulating gene expression is only beginning to be realized. Interestingly, more and more genes that can modify histones are being linked to tumor formation. The subsections below discuss the role of several key histone

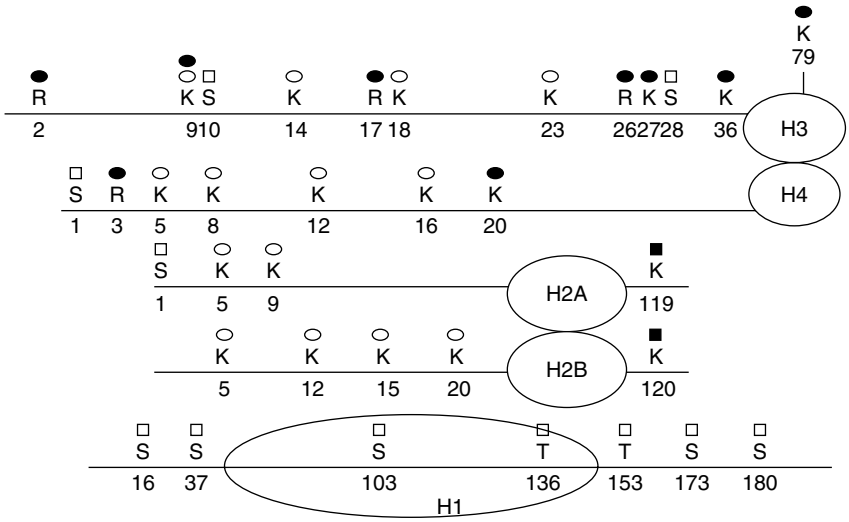

Fig. 4 Positions of modifications in the core histones and linker histone H1. Shown are the amino acids modified in each of the core histone tail regions, N-terminal tails to the left of globular domains and C-terminal tail to the right of globular domains in H2A, H2B, and H1. The types of modifications possible at each site are displayed above each amino acid. Phosphorylation (□), Methylation (●), Acetylation (○), Ubiquitination (■). Individual modifications can influence others in both facilitative and repressive ways.

modifications and the enzymes that catalyze their formation in mediating epigenetic regulation of gene transcription.

2.2.1 Histone Acetylation

Histone acetylation is known to be associated with, although not exclusively, transcriptionally active genes. Two classes of enzymes, histone acetyltransferases (HATs) and histone deacetylases (HDACs) are responsible for modifying the acetylation status of histones. These enzymes are often a part of larger protein complexes associated with transcriptional activation and repression respectively. Acetylation of the N-terminal tail of histones is thought to relax the DNA structure on the histone octamer and allow access to transcriptional machinery. Conversely, deacetylation of histones stabilizes a repressive chromatin structure. Acetylation of lysine residues has been documented in all core histones and at the N-terminus of linker histone, H1. Many of these enzymes are highly conserved in all eukaryotes including yeast, neurospora, and drosophila.

The first functional role of a HAT protein in gene transcription was identified in the yeast homolog of the Gcn5 transcriptional coactivator. Since then, several other proteins identified as transcriptional coactivators, many of which are included in Table 2, also have HAT activity. Currently, it is thought that histone acetyltransferases are recruited to chromatin through interactions with DNA sequence–specific transcription factors. However, acetylation activity can be targeted to specific DNA sequences when HATs also have DNA binding domains, as is the case for activating transcription factor-2 (ATF2). It is important to note that some HATs such

as CBP, P300, PCAF, and TAFII250 function to modify both histones as well as other members of transcriptional activation complex (Table 2). In the case of CBP and P300, other cellular targets for acetylation such as P53 have been identified and may be equally important in modifying gene expression.

While the acetylation of the core histones is most often studied in the context of transcriptional activation, acetylation plays many roles in chromatin biology. For instance, Lys5 and Lys12 residues of histone H4 are acetylated prior to chromatin assembly and are an important modification for facilitating assembly of newly replicated DNA into chromatin. Once replication completes, this acetylation pattern is erased and new acetylation pattern is established most likely in response to genetic positional information. Histones in transcriptionally active genes are most often acetylated at H3(Lys9) and H3(Lys14). Conversely, acetylation of H4(Lys12) in yeast and flies is found predominantly in heterochromatin or repressed chromatin.

Moreover, as discussed below, acetylation of histones can facilitate and/or repress methylation or phosphorylation of other histone residues and *vice versa*. Among these interactions emerges the critical importance assigned to H3(Lys9), that can be either acetylated or methylated, but not both at the same time, providing what may be a molecular switch point for recruitment of activation versus repression complexes to gene promoters.

Histone acetylation is a dynamic equilibrium resulting from the opposing activities of HATs and histone deacetylases (HDACs). HDACs are defined by genetics into subclasses based on homology to three yeast HDACs, *Rpd3* (Class I: *HDAC1*, 2, 3, and 8), *Hda1* (Class II: *HDAC4*, 5, 6, 7, and 9) and *Sir2* (Class III: *hSIRT1*-7). There are two well-characterized class I HDAC containing complexes, Sin3/HDAC and NuRD/Mi2/NRD that play known roles in transcriptional repression that is dependent on HDAC activity. While the class I HDACs localization in cells is predominantly nuclear, the class II HDACs appear to be shuttled between the nucleus and cytoplasm. Class II enzymes are not found as part of the same complexes as class I enzymes, but do interact with corepressors of certain transcription factors.

How might acetylation status of histones be conveyed to transcriptional machinery? One way could be that acetylation of histones loosens the DNA–histone contact points providing greater accessibility of transcription factors to critical regulatory sequences. Alternatively, regulatory proteins that directly recognize and bind to acetylated lysines may be recruited to acetylated histones. The protein motif that is known to recognize and bind acetylated lysines is called the *bromodomain*. A large family of bromodomain-containing proteins has been identified both functionally and through sequence homology and is included in Table 3. Many HATs themselves contain

Tab. 3 Bromodomain-containing proteins.

Gene	*Description/Function*	*Location*

bromodomains, including CREBBP, P300, PCAF, GCN5, and TAFII250. Several bromodomain proteins have unknown functions, but many others are known to play specific roles in chromatin remodeling such as Brg1 and Brm, the catalytic engines of ATP-dependent chromatin remodeling complexes. It is important to note that at least one bromodomain protein, BS69, has known roles in repressor complexes providing further evidence that acetylation may have multiple and diverse functions. One can clearly imagine that through bromodomains, the status of acetylation as a promoter can determine the presence or absence of many key factors in transcriptional control.

2.2.2 Histone Methylation

While methylation of histones was discovered more than three decades ago, its importance in gene regulation and chromatin condensation was not be realized until the late 1990s when researchers began to clone histone methyltransferases functionally from yeast and mammalian cell extracts. Unlike histone acetylation that is subject to the dynamic interplay of HAT and HDAC activity, histone methylation appears relatively static and to date no bona fide histone lysine demethylases have been identified. Methylation can occur on either arginine residues or lysine residues and is catalyzed by several different protein families (Table 4). Many of the lysine directed Histone methyltransferases (HMTs) contain SET domains named for the founding three members in *Drosophila*, Suppressor of variegation effect-39H1 (*Su(Var)3–9*), Enhancer of zeste (*EZH*) and trithorax (*TRX*). These original members of the SET-domain family were cloned by virtue of their influence on *Drosophila Hox* gene regulation (EZH and TRX), or position effect variegation, the concept that the physical nature of surrounding chromatin can dictate whether a gene is expressed or not (Su(Var)3–9). Eventually, the gene products derived from the human homologs of these alleles *Suv39H1*, *EZH2*, and *MLL* were found to possess histone methyltransferase activity. Families of arginine methyltransferases containing SAM binding domains are known to have many cellular targets in addition to histones. The arginine methyltransferase CARM1 was identified by its association with the histone acetyltransferase GRIP1 and preferentially methylates H3(Arg2), H3(Arg17), and H3(Arg36). Finally, the protein DOT1 that does not contain a SET domain or an apparent SAM binding domain methylates H3(Lys79) in the globular domain and may affect telomeric silencing specifically. Because most arginine and lysine methyltransferases utilize SAM as methyl donor, they are possibly subject to the same dietary influences of folate outlined above for DNA methylation (see Sect. 2.1).

Methylation of lysine residues in H3 and H4 tail domains has been associated with either transcriptional activation or repression depending on the residue modified. Methylation of H3(Lys4) is often associated with transcribed genes, whereas methylation of H3(Lys9) is almost invariably associated with heterochromatin. The SET-domain proteins SET7 and MLL both specifically target H3(Lys4) for methylation and this modification is associated with their ability to coactivate transcription. Several lines of evidence point to H3(Lys9) as an epigenetic mark that dramatically alters heterochromatin structure *in vivo*. First, methyltransferases that show specificity for H3(Lys9), such as Suv39H1, are often found in complexes containing HDACs and heterochromatin-associated

Tab. 5 Chromodomain containing proteins.

Gene	*Description/Function*	*Location*
CBX6	Chromobox protein 6	22q13.1
CBX7	Chromobox protein 7	22q13.1
CDY1	Testis specific chromodomain Y protein 1	q11.2
CDY2	Testis specific chromodomain Y protein 2.	q11.2
CDYL	Chromodomain protein Y-like	6p25.1
CHD1	Helicase, remodeling	5q15
CHD5	Chromodomain helicase DNA binding protein 5	1p36.31
HP1-alpha	Heterochromatin formation, transcriptional repression.	12q13.13
HP1-beta	Heterochromatin	17q21.32
HP1-gamma	Unknown	7p15.2
Mi2-alpha	Deacetylation complex	17p12
Mi2-beta	Deacetylation complex	12p13.31
PC2	Polycomb homolog 2	17q25.3
PC3	Polycomb homolog 3 (CHD8)	17q25.3
Q9BTP1	M-phase phosphoprotein 8	13q12.11
SUV39H1	Suppressor of variegation	Xp11.23
SuV39H2	Suppressor of variegation	10p13
RBP1	Retinoblastoma binding protein	14q22.3

proteins such as HP1. Additionally, cells derived from mice that lack Suv39H1 show decreased heterochromatin assembly and conversely, overexpression of Suv39H1 increases overall heterochromatin in cells. Using Tetrahymena, it has also been shown that mutations in the Suv39H1 homolog or mutation of H3(Lys9) can abolish all histone methylation in this organism.

Similar to acetylation, conveyance of histone methylation marks to the transcriptional machinery may occur through proteins that specifically recognize and bind methylated lysines. The chromodomain (*Ch*romatin *o*rganization *mo*difier) of HP1 protein specifically recognizes and binds to methylated K9 indicating this mark may recruit and/or maintain HP1 in heterochromatin regions. By sequence homology, many other proteins exist that contain chromodomains and it awaits to be seen if the chromodomain is a general motif for binding of methylated lysine residues in histone tails (Table 5).

The dynamic link between histone methylation and DNA methylation is supported by already mentioned correlations of H3(Lys4) and H3(Lys9) with undermethylated and hypermethylated genome regions respectively. Several scenarios arise through which there could be communication between histone modifications and DNA methylation via interactions with the respective enzymes (Fig. 5). First, proteins that recognize methylated cytosines, such as MeCp1, can recruit histone deacetylases to promoter regions (Fig 5(a)). A second possibility is that the methyl binding domains within or in conjunction with histone methyltransferases recognize methylated cytosines and initiate histone methylation (Fig. 5(b)). A third possibility is that chromodomain containing proteins such as HP1 can recognize methylated lysines within nucleosomes and subsequently recruit DNA methyltransferases to CpGs in promoters (Fig. 5(c)). It is important to note

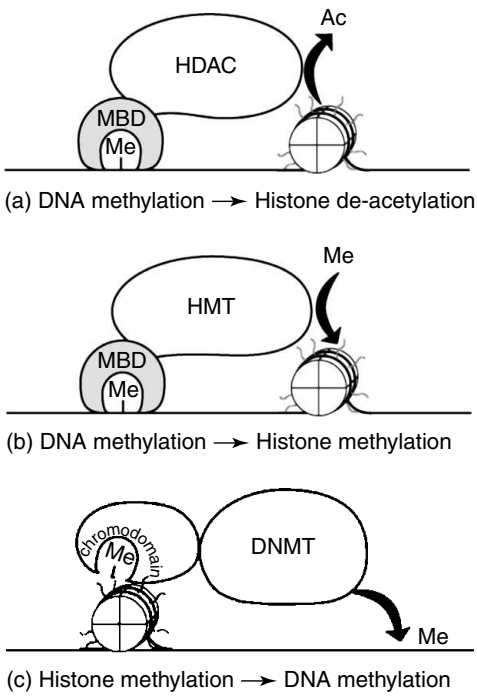

Fig. 5 Relationship between DNA methylation and histone modifications in transcriptional silencing. (a) Proteins with methyl binding domains (MBD; e.g. MeCp2) recognize methylated cytosines in DNA and recruit HDACs that catalyze histone deacetylation. (b) An MBD protein can also function to recruit histone methyltransferases, many of which function to repress transcription through methylation of histones (e.g Suv39H1 and Ezh2 resp). (c) Proteins with chromodomains (e.g. HP-1) recognize methylated lysines in histones and recruit DNAmethyltransferases (DNMT) to chromatin

that these scenarios are not mutually exclusive and that all may exist in a particular cell type or be specific for selected promoters.

2.2.3 Histone Phosphorylation

Phosphorylation of histones H3 and H1 is associated with chromosome condensation during mitosis. However, more recently, the phosphorylation of H3(Ser10) has been associated with activation of immediate-early-response genes such as *c-jun*, *c-fos* and *c-myc*. One H3 directed kinase Rsk-2 is mutated in human Coffin–Lowry syndrome. Phosphorylation of H3 is also catalyzed by MSK1, a kinase that is activated in response to growth factors *in vitro*. As shown in Fig. 4, the linker histone H1 contains up to seven residues that are targets for phosphorylation. The phosphorylation status of H1 undergoes distinct pattern changes throughout the cell cycle that may be regulated in part by the activity of CDK2, a protein kinase often hyperactivated in tumors. Interestingly, recent evidence suggests that phosphorylation status of H1 may influence SWI/SNF remodeling activity and gene activation of certain hormone responsive promoters such as the mouse mammary tumor virus (MMTV) promoter. Many phosphorylation events in histones act cooperatively with acetylation and antagonize methylation. For instance, *in vitro* H3(Ser10) phosphorylation facilitates acetylation of H3(Lys14), but antagonizes methylation of H3(Lys9). This role of H3(Ser10) in gene activation is counterintuitive to the role of phosphorylation in chromatin condensation and it may be that combinatorial changes in other histone modifications may also participate in

this process. Furthermore, sites and levels of phosphorylation in H1 do not appear to be equivalent and the presence of several isoforms of H1 may play specific and contrasting roles in gene activation rather than condensation.

2.3 RNA and Posttranscriptional Silencing

We must also consider another emerging player in epigenetic regulation. Over the past several years, the role of RNA and specifically short RNAs in critical biological processes has become increasingly clear. In plants, *Caenorhabditis elegans*, and neurospora, double-stranded RNAs (dsRNA) sliced into shorter products were shown to target homologous RNA for cleavage and degradation. Researchers immediately recognized the utility of such an endogenous system to allow functional knockouts in these organisms without altering genomic DNA sequence. Called *RNA-interference*, or *RNAi*, this technology can now be performed in mammalian cells with moderate success using short recombinant RNA. The concept of using small interfering RNAs to knockdown gene expression has tremendous translational value as these RNAs may be easier to deliver than typical viral or DNA based gene therapies without as many side effects.

RNA is also an important endogenous modifier of gene expression in mammalian cells. The regulation of two loci, the *H19* and *Xist-Tsix* loci provided the first indication that RNA may play a significant role in epigenetic gene regulation. Both loci code for untranslated RNAs. The *Xist* RNA is required for initiation of X chromosome inactivation and is regulated by balanced expression of *Tsix*. Through gene knockout studies in mice, *H19* RNA is shown to be required for the maintenance of imprinting at several somatic loci. It stands to reason that RNAs such as those generated from *H19* or *Xist* may in fact be structural parts of chromatin. Indeed, in plants, double-stranded RNA functions to mark homologous DNA sequences for methylation and subsequent silencing. Furthermore, in mammalian cells, it is known that the heterochromatin around centromeres is more stable and requires more prolonged treatment with HDAC inhibitors to remove HP1 and relax the chromatin in this region. In a remarkable discovery in 2002, this phenomenon was shown to be dependent on an as-yet-unidentified nuclear RNA since cells that were treated with RNAse rapidly lost HP1 from pericentric chromatin. This result will inevitably lead to a better mechanistic understanding of previous unexplained roles of RNA in epigenetic regulation. This structural role of RNA in chromatin and its impact in tumor development will be a new area of intense research in the years to come.

3 Epigenetics and Tumorigenesis

3.1 Methylation-mediated Silencing in Tumorigenesis

DNA methylation impacts tumor formation by both silencing of methylation-sensitive genes and increasing mutation rates in genes due to spontaneous deamination of methylated residues. For an example of the latter, CpG dyads in P53 are often methylated in normal human tissues and a small number of these CpG dyads account for or are adjacent to the majority of P53-inactivating mutations. While the spontaneous deamination mechanism is

hypothesized to be the most likely cause of CpG mutations, alternative explanations include carcinogen sensitivity and enzyme directed methods of mutating methylated genes (see Sect. 2.1). Alleles that are targets for hypermethylated-mediated silencing in tumors include many genes involved in cell-cycle progression (*P16^{INK4a}*, *Rb*, *P14^{ARF}*, *P73*, *ER*), DNA repair, (*MLH1*, *B4RCA1*), carcinogen metabolism, (*GSTP1*), cell adhesion and metastasis (*CDH1*, *CDH13*) and apoptosis (*DAPK*, *TMS1*). Promoter hypermethylation of some of these tumor suppressor alleles appears to be specific for certain tumor types, as is the case of p73 in lymphoma and BRCA1 in breast cancer. Many targets of methylation associated silencing have clear ties to tumor progression and are included in Table 6.

Many initial studies that mechanistically link methylation to cell growth are the result of analyzing tumor suppressor promoter methylation in tumor cell lines. The evidence that tumor suppressor CpG–island hypermethylation may be an early event in tumor formation is derived from studies on pre-neoplastic and tumor biopsies and resections. The number of alleles associated with methylation-induced silencing continues to grow. For the purpose of this article we have chosen, as archetypes, alleles for which significant progress has been made in determining tumor suppressive mechanism in cells and tumors and which we feel are particularly good examples of the many roles of DNA methylation in tumor formation. Table 6 lists additional known tumor-related genes influenced by methylation and includes information for accessing a database maintained by the National Library of Medicine where additional information for each gene can be found.

3.1.1 Methylation of Genes Involved in Cell-cycle Control

The cyclin dependent kinase inhibitor, CDKN2 or P16^{INK4a}, protein functions by inhibiting cyclin dependent kinases 4 and 6 (Cdk4 and Cdk6) thus inhibiting the phosphorylation of pRB and progression of the cell cycle. The *P16^{INK4a}* gene in tumors is subject to point mutations, deletions, and methylation, and the array of alterations varies by tumor type. The first observation of hypermethylation of the *P16^{INK4a}* CpG island in tumors was made in 1995. Work that followed has identified *P16^{INK4a}* promoter methylation in all tumor types examined. Recent work published in 2003 examined silencing of the *P16^{INK4a}* promoter in a colon tumor cell line and found that DNA methylation is required to maintain silencing of *P16^{INK4a}*. However, *de novo* methylation associated with the silencing of *P16^{INK4a}* promoter was actually preceded by histone methylation. This work provided an interesting new logic behind both the interplay as well as independent actions of these two epigenetic marks.

Familial adenomatous polyposis (FAP) is a familial condition resulting in multiple polyp formation in the lower GI tract and a predisposition of these polyps to develop into carcinoma. The adenomatous polyposis coli (*APC*) gene is located at chromosome 5p21 and mutations can result in the autosomal dominant familial FAP as well as sporadic cancers. However, not in all FAP cases could mutation be detected and in 18% of those that are not mutated, aberrant hypermethylation of the 5′CpG island occurs in association with reduced expression. Loss of APC function results in loss of degradation of the transcriptional activator and oncoprotein β-catenin, leading to increased cell cycle and growth. While the study of

Tab. 6 Expressed genes affected by promoter methylation status.

Gene	*Function*	*Location*	*Tumor types*	*OMIM*[a]
Cell cycle and apoptosis				
TP73	p53 homolog	1p36	Lymphoma, leukemia	601990
P15	Cyclin dependent kinase inhibitor	9p21	Leukemia	600431
P14	MDM2 inhibitor	9p21	Colon, stomach, kidney	600160
P16/INK4a	Cyclin dependent kinase inhibitor	9p21	Multiple	600160
RB	Cell-cycle inhibitor, transcriptional repressor	13q14	Retinoblastoma, multiple	180200
APC	Inhibitor of β-catenin	5q21	Digestive tract	175100
ER	Estrogen receptor	6q25	Breast	133430
DAPK	Kinase, mediator of interferon induced apoptosis	9q34	B-cell lymphoma, lung, colon	600831
STK11/LKB1	Serine/threonine kinase, interacts with p53	19p13	Colon, breast, lung, ovarian	602216
TMS1	Proapoptotic	16p11	Breast	606838
IGF2	Growth factor	11p15	Multiple	147470
TMEFF2/HPP1	Transmembrane protein	2q33	Colon, bladder	605734
DNA Repair				
MLH1	DNA mismatch repair	3p21	Colon, endometrium, stomach	120436
BRCA1	DNA damage repair, transcription, X-inactivation	17q21	Breast, ovary	113705
MGMT	Repairs DNA guanosine-methyl addcuts	10q26	Brain, colon, lung, lymphoma	156569
RASSF1A	RAS effector homolog, DNA repair	3p21	Multiple, lung	605082
Metastasis				
CDH1	E-cadherin, cell–cell adhesion	16q21	Breast, stomach, thyroid, leukemia	192090
TIMP3	Extracellular matrix degradation and cell migration	22q12	Colon, renal, brain	188826
CDH13	H-cadherin, cell adhesion	16q24	Breast, lung	601364
Metabolism				
GSTP1	Conjugation of glutathione, prevention of oxidative damage	11q13	Prostate, breast, kidney	134660

Each number is unique identifier of gene-specific information including a review of relevant clinical and basic research and up-to-date links to pertinent primary literature.

APCs involvement in colon polyp and tumor formation led to the identification of methylation as a potential factor, the role for methylation in the progression of polyps to tumors may have been best shown using a mouse model of APC. The APC^{-min} allele in mice is a functional null allele discovered in a mutagenesis screen for colon polyp formation. These animals produce multiple polyps that progress to tumors similar to humans. The *DNMT1* status is a determinant in polyp-formation susceptibility in the APC^{-min} animals. When animals deficient in one copy of *APC* ($APC^{min/+}$) were mated to mice deficient in DNMT1 activity, the resulting animals had reduced intestinal adenomas compared to $APC^{min/+}$ animals with normal DNMT1 activity. This result is concomitant with decreased CpG-island methylation indicating that this decrease in methylation may be the protective mechanism against polyp formation. Therefore, it is possible that treatments to decrease methylation in colon cells may be effective against tumors associated with loss of APC.

The estrogen receptor (ER) is a hormone activated transcription factor that plays a necessary role in cell proliferation of estrogen-responsive tissues such as the uterus and mammary epithelium. In cell lines that have lost ER, readdition of ER protein results in growth inhibition indicating that loss of ER expression in preneoplastic tissues may provide a growth advantage. Estrogen receptor gene has two promoters associated with CpG islands and age-related methylation. Increases in CpG-island methylation at *ER* is linear with age, increasing in human colon tissue from 2 to 20% through the second to the ninth decades of life. Moreover, the degree of methylation is progressive in prostate and colon tumor formation and is consistent with a selective advantage for this modification. Thus, silencing of *ER* is one example of several alleles, also including *MYOD1*, *N33*, and *Pax6*, that undergo both age-related methylation and selection for methylation-induced silencing in tumors. The status of ER in tumors is an important factor in tumor treatment strategies. The loss of ER in breast tumors is often associated with more aggressive cancers and negative clinical outcomes. ER-negative tumors are not responsive to tamoxifen, an anti-estrogen drug found to be a highly effective treatment in ER-positive breast tumors. Furthermore, tumors that escape doxorubicin treatment have often lost ER expression indicating that this particular treatment for ER sensitive tumors may predispose the tumor to become more aggressive. Therefore, the ability to reactivate a silenced ER in tumor cells could be an important advantage in treatment strategy.

The P73 protein is similar in sequence and secondary structure to P53, a known regulator of cell-cycle progression and DNA-damage induced apoptosis. However, the role of P73 may be different and its mechanism of action is not entirely understood. Interestingly, *P73*-promoter hypermethylation is predominant in B-cell and Burkitt's lymphoma; more prominent than mutation or LOH. Among many tumor types, lymphomas and leukemias are the only ones in which *P73* methylation has been detected. It remains to be seen whether methylation of *P73* is causative or correlative in tumor progression in these tissues and why methylation is a more prominent form of P73 inactivation in blood tumors versus solid tumors. One possible reason for this tissue specificity is that normal lymphocytes are imprinted at *P73*, so loss of only the expressed copy

would be necessary to eliminate P73 protein in these cells.

3.1.2 Methylation of Metastasis-related Genes

The E-cadherin protein (CDH1) functions in calcium-dependent cell–cell adhesion and loss of CDH1 in tumors is highly correlated with tumor metastasis, especially in epithelial-derived tumors. While mutations in E-cadherin are found in a few subsets of tumor types, most often, inactivation of E-cadherin occurs through promoter methylation. Methylation frequency is very high in all sporadic tumors examined, including breast, leukemia, and esophageal, at an incidence often greater than 40%. Interestingly, methylation of *CDH1* is inversely correlated with LOH in epithelial tumors and often E-cadherin expression is reactivated in the metastasis indicating that reversal of the *CDH1* silencing is an important part of epithelial tumor progression. Other genes involved in metastasis that are associated with methylation-induced silencing include tissue inhibitor of metalloproteinases (*TIMP3*) and H-cadherin (*CDH13*) (Table 6).

3.1.3 Methylation of DNA Repair Genes

Virtually all cases of hereditary nonpolyposis colon carcinoma (HNPCC) and 13% of sporadic colon carcinomas display genomic microsatellite instability (MSI). The hallmark of MSI are changes in the length of individual single and dinucleotide repeat sequences throughout the genome due to slippage of the replication complex, and failure of the mismatch repair system. When such a repetitive sequence occurs in the coding sequence of a gene, this slippage often results in frameshift mutations. The human homologs of *Escherichia coli mutL* gene, *MLH1* and *MLH2*, are major factors in mismatch repair and hypermethylation-induced silencing of the *MLH1* promoter is found in a majority of colorectal cancers with MSI. Because MLH1 protein is critical in DNA repair, when mutation or silencing occurs, the effect can be genome-wide. Given these associations, it is suspected that a deficiency in methylation activity would be protective against formation of these tumors. When *MLH1* deficient mouse models were made to be deficient in *DNMT1* by mating to a hypomorphic *DNMT*-1 mouse, two opposing results were obtained. First, the incidence of intestinal cancers was decreased consistent with data obtained in human patients interlinking increased DNA methylation concurrent with MSI. However, in these same animals there is a dramatic increase in the incidence of lymphoid tumors. These results indicate that the role of DNA methylation in intestinal cancers is distinct from that involved in lymphoid tumor formation.

BRCA1 is mutated in almost half of familial linked breast cancer cases, although few mutations have been described in sporadic breast cancer. However, recent data indicate that a significant portion of sporadic ovarian and breast tumors are methylated rather than mutated for *BRCA1* and this modification is often associated with LOH. Similar to *P73*, *BRCA1* inactivation by methylation is highly tissue-specific with no methylation reported to be associated with *BRCA1* in colon, leukemia or liver tumors. While the role of BRCA1 protein in either normal cells or progression to tumor cells is poorly understood, BRCA1 protein has been reported to interact with several proteins involved in DNA repair and recombination, implicating a role in mediating this process. Importantly, a recent and

particularly interesting observation indicates a role for BRCA1 in targeting the *Xist* RNA to the X chromosome. In this study, cells that lack BRCA1 were shown to have abnormal X-inactivation and loss of focal H3(Lys9) methylation along the inactivated X chromosome. It will be of interest to determine if BRCA1 plays a more global role in RNA-mediated alterations of chromatin structure such as the recent discovery of RNA-mediated pericentric heterochromatin formation.

BRCA1 represents an example of the impact of promoter methylation on gene activation by interference with specific transcription factor binding (see Fig. 3(b)). In this case, the screening of a series of randomly sampled breast carcinomas revealed the presence of CpG methylation adjacent to the *BRCA1* transcription start site, whereas in control normal tissues these same regions were unmethylated. One such methylated CpG occurs at a CREB (cAMP-responsive element binding) transcription factor binding site in the *BRCA1* promoter. Methylation prevents binding of CREB and the recruitment of transcription factors leading to downregulation of *BRCA1* in a breast tumor cell line. Thus, one possible mechanism of transcriptional inactivation of the *BRCA1* gene within breast tumors may be interference due to methylation of this specific sequence rather than CpG-island hypermethylation and subsequent heterochromatin formation.

3.1.4 Methylated DNA Binding Proteins

The MBD4 protein interacts *in vitro* with MLH and is thought to participate in DNA mismatch repair by removing thymine or uracil from mismatched CpG sites. Mutations in MBD4 are found in colorectal carcinomas, tumors with microsatellite instability, endometrial, and pancreatic tumors with 20 to 25% incidence. A microsatellite ''hotspot'' in a polyadenine tract in the MBD coding region is often the site where mutations are found. A mouse model deficient in MBD4 had a threefold increase in C to T transitions in CpG dinucleotides throughout the genome. When crossed to APC^{min} allele, MBD4 deficiency increased rate of tumor formation and mutability of *APC* gene. Together these results indicate that MBD4 is required to suppress C to T transitions presumably by recognizing methylated Cs in the parent strand during mismatch repair.

3.2 Histone Modifications in Tumorigenesis

Evidence of the importance of histone-modifying proteins as epigenetic regulators of transcription, chromatin structure, and tumor formation is increasing. Indeed, as mentioned above, silencing of the cell-cycle control protein $P16^{INK4a}$ may be initiated through histone modifications prior to DNA methylation. Here we outline specific examples of known roles that these proteins play in human disease and some of the mouse models generated in attempts to gain more insight into the functions of these proteins. Proteins that modify histones can be inactivated in tumors by point mutation, deletion, translocation, and in some cases methylation. Interestingly, some translocations involving HATs and HMTs result in proteins that gain new functions leading to tumors.

3.2.1 Histone Methyltransferases

By a microarray approach the overexpression of the SET-domain histone methyltransferase EZH2 was recently found to be highly correlated with metastatic prostate tumor tissues as compared with

benign prostate or localized prostate tumors. EZH2 has a SET domain and has recently been shown to have bona fide histone methyltransferase activity targeting H3(Lys27) in nucleosomal DNA. EZH2 associates with HDACs in a complex that also contains the WD-repeat protein EED that is important in maintenance of imprinted X-inactivation. Negative regulation of gene expression in prostate tumor cell lines by EZH2 is dependent on an intact SET domain and HDAC activity. Furthermore, repression of EZH2 in prostate tumor cell lines reduced their cell growth.

Another histone methyltransferase, Suv39H1, is implicated in tumorigenesis by virtue of interaction with Rb in the progression of the cell cycle. The ability of Rb to block E2F transcription of the cyclin E promoter is mediated in part by HP1 and Suv39H1. Suv39H1 exhibits cell-cycle dependent changes in activity, such that it is active in G1, but becomes inactive during G1–S-transition and is reactivated late in S-phase. Although a definitive role of this allele or its homolog *Suv39H2* in human primary tumors has not been demonstrated, results from gene targeting in mice implicates one. Null alleles of *Suv39H1* and *Suv39H2* as well as transgenic animals that overexpress Suv39H1 have been characterized. The results from phenotypic and chromatin analysis of these models is consistent with a role for Suv39H proteins in heterochromatin formation and uncovered a role for Suv39H in chromosomal segregation during mitosis. Individually, *Suv39H1* and *Suv39H2* null mice do not display abnormal phenotypes and are fertile. However, *Suv39H1/H2* double-knockout mice develop late onset B-cell lymphomas that resemble non-Hodgkin's lymphoma in humans. Primary fibroblast cells lacking Suv39H1 and H2 quickly become aneuploid and are prone to aberrant mitosis and chromosomal segregation. Furthermore, mitotic profiles of H3(Lys9) methylation are severely altered or diminished in both fibroblast and bone marrow cells. Overexpression of Suv39H1 in transgenic animals impairs differentiation but, remarkably, can also lead to spontaneous immortalization without crisis in fetal hepatocytes and erythrocytes. The SET domain is also known to be a protein–protein interaction motif and in some cases this may be the primary function of this domain. It remains to be seen if chromatin targets or other cellular targets may be responsible in increasing tumor transformation in these animals.

RIZ1 is a zinc-finger and SET-domain containing tumor suppressor gene identified by virtue of its interaction with Rb. The location of *RIZ1* in the human genome is 1p36, a region often deleted in human cancers. *RIZ1* frame-shift mutations are found in 37% of microsatellite-instable tumors and the *RIZ1* promoter is also a target for hypermethylation-mediated repression. The *RIZ1* locus codes for two protein products, RIZ1 and RIZ2 that are controlled by separate promoters. RIZ2 is smaller than RIZ1 and lacks the SET-domain. Importantly, RIZ1, but not RIZ2 expression is lost in breast cancer, lung cancer, osteosarcoma, hepatoma, neuroblastoma, and colon cancer indicating that the SET-domain portion of RIZ1 is important in its tumor suppressor role. Although RIZ1 contains a SET domain and interacts with several transcription factors including Rb, ER, and GATA3, an HMT activity has not yet been demonstrated. The generation of a null allele of *Riz1* in mice provided perhaps the best evidence of its role as a tumor suppressor. Homozygous *Riz1*-null animals are viable and fertile, but

have increased incidence of multiple tumors especially diffuse B-cell lymphoma, one of the most common non-Hodgkin's lymphomas found in humans. Investigators showed that in cell lines that lack RIZ1, exogenous addition of RIZ1 significantly slowed growth both in cell culture and in the capacity of cells to form tumors when injected subcutaneously into mice. Gene therapy attempts in mice that target MSI+ tumors using RIZ1 expression vectors are encouraging.

The gene for another SET-domain containing protein, *MDS-EVI1* is located in a region of chromosome 3 often involved in translocations in myeloid leukemias. Similar to RIZ1 and RIZ2, the EVI1 and MDS1 protein products are also derived from the same locus under different promoter control. In this case, MDS1-EVI1 contains a SET domain and zinc-finger domain, whereas EVI1 lacks the SET domain. EVI1 acts as an oncogene when found in translocation products acting to increase growth rates in tumor cell lines. However, expression of the *MDS1-EVI1* gene product represses growth. A transgenic mouse model was generated to express the translocation produced *MDS1-EVI1-AML* fusion only in the blood cells. These mice die quickly of acute myelogenous leukemia and can serve as a model system to understand progression and treatment options for this type of leukemia. As with RIZ1, the presence of the SET-domain has not yet been associated with histone modifications.

Many SET-domain proteins are involved in translocation events in tumors. Mixed lineage leukemia (MLL) susceptibility mapped in humans at chromosome 11q23 was subsequently shown to code for the homolog of *Drosophila* TRX protein, a SET-domain containing protein (see Sect. 2.2.2). MLL may present an example of the cross-talk between histone modifications and the SWI/SNF complexes. MLL is a transcriptional effector that targets H3(Lys4) for methylation and has been shown to directly interact with SNF5 and Brg1. The human *MLL* allele is involved in as many as 30 different translocations found in 80% of infant leukemias. These translocations are thought to result in a gain of function for MLL because of the activity of the fusion. Consistent among these translocations is that the new product retains the amino-terminal 1300 amino acids, but loses the plant homeobox domain (PHD), transactivation, and SET domains of MLL. The exact role of many of the fusions in tumorigenesis is yet to be determined, but one recent suggestion noted from experiments using mouse *Mll*-null cells is that the mutant fusions involving *MLL* may cause cells to bypass cellular differentiation–induced downregulation of MLL-targets such as *Hox* genes.

3.2.2 Histone Acetyltransferases

Misdirection of HAT activity occurs as a result of several chromosomal translocations involving HATs. Among the HATs most commonly associated with tumorigenesis is the CREB binding protein (CBP). CBP is a large protein with many functional domains including three putative zinc-finger interaction motifs, an acetyltransferase domain, a plant homeobox domain, and a bromodomain. The locus that codes for CBP, *Crebbp*, is involved in several translocation events. Among these are translocations that create fusions with either *MOZ* (monocytic leukemia zinc-finger protein, t(8;16)(p11;p13)) or *MLL* (t(11;16) (q23;p13.3)) associated with leukemia. Translocations of *Crebbp* involving either *MOZ* or *MLL* result in fusion proteins that gain novel functions that may result in aberrant histone

acetylation. Loss-of-function mutations in *Crebbp* result in the multisymptom Rubenstein–Taybi syndrome associated with an increase in tumor incidence, especially leukemias. Mice that lack CBP also display many of these same symptoms including a predisposition to leukemias. Furthermore, truncations and LOH associated with P300, an acetyltransferase and close homolog of CBP, is implicated in gastric cancers and glioblastomas. It is important to note that both CBP and P300 are known to acetylate many proteins in addition to histones including P53 and other members of the general transcriptional machinery. Thus, the exact role of histone substrates in mediating tumor formation associated with these proteins is unclear.

The ''*a*mplified *i*n *b*reast protein'', AIB1, (ACTR/pCIP/TRAM1/RAC-3/SRC-3) is a member of the P160 subfamily of histone acetyltransferases and was found during a search for genes amplified in breast tumors. AIB1 overexpression is found in more than 60% of breast tumors analyzed and enhances steroid receptor activity by interaction with the steroid receptors themselves. In some cases, amplification of AIB1 is associated with loss of steroid receptor expression or function, which could be a factor in treatment outcomes when using antiestrogens, such as tamoxifen. It is also overexpressed in prostate tumors, ovarian, pancreatic, endometrial cancers, and primary gastric tumors, and is associated with metastases and poorer prognosis. A *Drosophila* homolog of AIB1 was shown to affect cell–cell contact and focal adhesion, but its role in mammalian biology is not completely understood.

The role of HDACs in tumor formation derives from the aberrant targeting of HDACs to promoters as a result of fusions between unrelated transcriptional activators and transcriptional repressors. For example, a transcription factor such as retinoic acid receptor alpha (*RARA*) when fused to promyelocytic leukemia, (*PML*) [t(15;17)(q22;q21)] is no longer hormone responsive, and recruits HDACs to retinoic acid response elements in DNA leading to repression of retinoic acid mediated gene expression and acute promyelocytic leukemia. Conversely, other fusions of AML (Acute myelogenous leukemia) with the transcriptional regulators *TEL1* [t(1;12)(q21;p13)] or *ETO* [t(8;21)(q22;q22)] convert AML from activator to repressor via a gain of HDAC recruitment in the fusion proteins. The role of HDACs in the consequences of these fusions identifies these types of tumor events as good targets for HDAC inhibitor–based treatments.

3.3 Imprinting and Tumorigenesis

Expression of the Wilms' tumor gene, WT, located on human chromosome 11p, is lost in most cases of sporadic and familial Wilms' tumor, a common embryonal tumor that affects the kidney. Within this region of 11p is a cluster of imprinted alleles. In Wilms' tumor-associated LOH on chromosome 11p, there is significant bias for loss of the maternal allele. This implies a growth advantage for the loss of a maternally expressed allele near the *WT* allele. Candidate alleles include the maternally expressed H19 RNA. The paternally expressed insulin-like growth factor 2 (*IGF2*) and *H19* are coordinately regulated in part by differential DNA methylation in a common promoter region. Failure to maintain imprinting at a region of chromosome 11p also leads to biallelic expression of the normally maternally silenced *IGF2*. This effect is tightly linked to the loss of maternally expressed, growth-inhibitory *H19* allele in Wilms' tumor. While early investigations

focused mainly on embryonal and childhood tumors, more recent studies have found that loss of imprinting of IGF2 is associated with most other tumors including hepatocellular, colorectal, brain, and testicular cancers.

3.4 Mouse Models

The ability to manipulate the genome of the common house mouse by gene targeting and transgenesis has propelled the mouse to the forefront in genetic modeling of human disease. Mice are not particularly susceptible to tumor formation and are particularly resistant to tumor metastasis, presumably because of a shorter life span. Therefore, small increases in tumor incidence in mice can be a strong indicator of the importance of a particular process in tumor formation. Conversely, lack of tumor growth can lead to an underestimation of a particular gene's importance. Furthermore, often the spectrum of tumor types resulting from a given mutation in mice is different from those in humans. Therefore, it is critical that results from animals be accepted only in the context of supporting human data from actual tumor biopsies. Nonetheless, the fact that mice get spontaneous tumors at any frequency warrants the development of the mouse as a tool in the war on cancer. Increasing use of methods such as viral oncogene delivery and transgenesis are beginning to ''humanize'' the mouse in tumor processes. Further development of humanized tumors in mice should have a significant impact on our understanding of tumor progression and treatment research in the future.

In addition to the animal models discussed in the above sections, null alleles have been generated for genes that are affected by methylation such as in *p16*, *p73*, *BRCA1*, *MLH*, *MLL*, *ERα*, and *CDH1*, all revealing their importance in development and tumor suppression. Models have also been generated at alleles for proteins responsible for modification of histones such as *CBP*, *P300*, *GCN5*, *PCAF*, and *G9a* and remodeling proteins such as *Brg1* and *Snf5*. In many mouse models, a heterozygous genotype is not enough to change tumor incidence and often homozygous null genotypes are embryonic lethal. While embryonic lethal phenotypes underscore the importance of a gene in developmental biology, this phenotype prevents the ability of researchers to determine roles of alleles in tumor formation. Many creative ways to circumvent embryonic lethality have been employed including conditional mutagenesis using the Cre-LoxP system of recombination to direct a null genotype to only a single tissue type. In order to determine whether the lack of tumors indicates a protective role, comparisons of phenotypes on tumor-model backgrounds, as done in the case of *Dnmt1* and the crosses to the APC^{min} and *Mlh1* mutant animals, is required (see Sect. 3.1.1 and 3.1.2).

Derivation of homozygous null ES cells and primary embryonic fibroblasts from mice carrying mutations important in establishing and maintaining epigenetic marks can give insight into cell autonomous functions in culture. The use of ES cells in studies of effects of mutations on growth and differentiation has become a welcome trend. ES cells maintain properties of tumor cells such as the ability for continual growth in an undifferentiated state. However, ES cells are stably diploid and lack the plethora of mutations found in most tumor cell lines. Additionally, the capacity of ES to be differentiated into many different cell types will allow definition of a specific role for a mutated gene in

a differentiation-mediated process, not the least important of which includes growth inhibition. For example, the roles of either DNMT1 or the histone methyltransferase G9a in growth only became apparent in differentiated (neuralized) ES, rather than in undifferentiated ES cells indicating a more important role for these proteins in differentiated cells. Furthermore, cell culture models, derived from mutant animals, offer an excellent environment to test the role of epigenetics in foreign DNA recognition and genomic incorporation.

4 Clinical Considerations

4.1 Detections

Methylation of certain promoter regions appears to be an early mark in tumorigenesis. For instance, promoter methylation of $P16^{INK4a}$ is detected in some colorectal adenomas and other precancerous lesions prior to development of the carcinoma. Therefore, it becomes of great importance to further our knowledge of genes, that when methylated can be termed markers of pre-neoplastic tissue, and methods of rapidly determining these changes in small amounts of tissue or body fluids. There are advantages of using methylation rather than classical mutation as a marker for pre-neoplasia. In this regard, mutations occur in many different forms and locations throughout a gene sequence, whereas methylation is specific to CpG dyads and is localized to a relatively small area of a locus. However, hypermethylation is not a ubiquitous characteristic in all tumors, and therefore must be used in conjunction with other neoplastic detection strategies including P53 status. On the other hand, in MSI + tumors where P53 is often normal, methylation status may have the best association with tumor potential.

Many experimental methods have been developed to detect either regional or genome-wide CpG methylation patterns. Excellent and detailed protocols regarding many aspects of methylated DNA were published recently as part of the Methods in Molecular Biology series (see Bibliography). Perhaps the simplest method to detect methylated cytosines in the genome is to take advantage of a reaction between bisulphite and unmethylated cytosines that causes conversion of the cytosine to uracil. Cytosines that are methylated are insensitive to bisulphite. Following treatment of DNA with bisulphite, DNA is amplified by PCR incorporating thymidine in place of the converted uracil. Currently, there are two widely used ways to detect the conversion events. One way that is becoming more popular as reagents become less expensive, is to subclone PCR-products and derive the DNA sequence to look for changes of C's to T's versus a control reaction. This provides a snapshot of all methylated changes within the region amplified and allows quantitation of the number of alleles in a population that are methylated. Another method to detect methylated cytosines is to use specific PCR primers that distinguish between unmethylated cytosines and the bisulphite mediated change. The advantages of this method are cost-effectiveness and rapid results, although the disadvantage is its ability to only detect a single change per reaction. There are additional ways to detect methylated cytosines without bisulphite including the use of methylation-sensitive restriction enzymes directed at specific sites in a promoter followed by Southern blot or ligation-mediated PCR.

In order to gain insight into different methylation patterns of specific tumor types, many researchers use these methods in the candidate gene approach to examine methylation of specific tumor suppressors. Because of the large body of work that had identified tumor suppressors subject to methylation and the sites of these aberrant methylations, this approach has yielded significant insights, for example, into designing new markers for MSI(+) tumors. While the candidate gene approach has yielded many promising leads, it can only render an incomplete picture. The availability of drugs to block promoter methylation, and the availability of cDNA microarrays has allowed more broadly based approaches that provide information not necessarily about promoter methylation, but the downstream effects methylation has on physiology. Such approaches have led to important discoveries in finding additional methylation-sensitive marker alleles, such as those noted above, linking increased EZH2 expression and progression of prostate cancer. Analysis such as these will yield potential PCR-based diagnostics easily adapted to the clinical lab. In addition to gene expression pattern changes, it is also possible to use large-scale methods such as DNA microarrays to detect the presence of methylation at specific promoters. To accomplish this, microarrays of CpG-island sequences derived from the genome database can be hybridized with tumor DNA digested with methylation-sensitive enzymes. The results can detect changes between methylation status in normal and tumor tissues at thousands of CpG islands that may be included in the array.

While the methods outlined above require prior knowledge of sequences of interest, there are also several ways to isolate unknown differentially methylated regions or obtain a global picture of the methylation status in cells. So-called genome-wide approaches include restriction landmark genome scanning in which total genomic DNA is first digested with a methylation-sensitive enzyme, then digested with methylation-insensitive enzymes, and separated in two dimensions. Fragments that differentially migrate can be isolated from the gels and subcloned for identification. A significant advantage of this approach is that it can be adapted to detect LOH in addition to methylation within the same tumors. Restriction landmark genome scanning in combination with computer-aided mapping of the recently completed human genome sequence has been used to successfully identify differentially methylated and deleted genes specific for brain tumors. Moreover, using such genomic approaches, as well as the candidate gene approach, the resulting profile of genes aberrantly methylated in a given tumor may provide a window into the biology of the tumor and allow tailoring of treatment strategies.

Methods for determining histone modification status pose a different set of problems. Possibly the most promising method for detection of global levels of certain histone marks is through the development of antibodies to histone tail domains that contain specific modifications. Antibodies have been developed that specifically recognize methylation, phosphorylation, and acetylation on the individual core histones. The correlation between global levels of these marks and neoplastic status of cells is yet to be determined. Methods that can detect marks on specific loci include chromatin immunoprecipitation where these same antibodies are used to precipitate chromatin followed by gene-specific PCR to determine the quantity of a region that is immunoprecipitated. While they

are promising, the current methods require more material than most standard biopsies provide and are time-consuming. The use of mass spectrometry to detect the phosphorylation status of histone H1 has successfully been used to look at the global dephosphorylation of H1 in cells in response to drug treatments such as dexamethasone. Given the differences in mass of acetyl, methyl, and phospho groups, it is likely that a mass spectrometry method could be adapted to detect the status of these marks on all histones. For histone modifications to be utilized in diagnostics, however, will require that researchers crack the ''histone code'' and be able find histone modifications that are relatively stable and clonal in tumor populations similar to DNA methylation.

4.2 Treatments

4.2.1 DNA Methyltransferase Inhibitors

The drug 5-Azacytidine (5-Aza) was first discovered to have antimetabolic activities and to be an effective therapeutic agent for acute myelogenous leukemia in the late 1960s and early 1970s. Incorporation of 5-Aza and an analog 5-Aza-2′deoxycytidine (5Aza2d) into DNA in the place of methylated cytosines results in an irreversible binding and inhibition of DNMTs. Unfortunately, this irreversible binding of DNMTs leads to DNA damage. In tumors that have lost the DNA-damage response mechanisms, many more mutations can be clonally introduced into the tumor genome following 5-Aza treatments. Because of the role of P53 protein in initiating cell-death in response to DNA damage, it is not surprising that it was discovered in leukemias, since p53 positive tumors are the most responsive to 5-Aza treatments. Another phenomenon observed following 5-Aza treatment is that cells tend to remethylate DNA over time. Recently, analysis of resilencing of the $P16^{INK4a}$ promoter following demethylation in a colon tumor cell line indicates that histone modifications may initiate this process.

Using DNA microarray technology and differential display, it is known that only a 1–2% change in genome transcription occurs with treatment of tumor cells with 5-Aza indicating that not all hypermethylated alleles are reactivated. However, the modest increases that occur following 5-Aza can be further induced by cotreatment with HDAC inhibitors. While HDAC inhibition alone is not enough to overcome DNA-methylation induced silencing, these results may have greater meaning when evaluating the efficacy of HDAC inhibitors in the future in combination with 5-Aza (see below).

Besides 5-Aza, other agents are being researched for more specific downregulation of DNMTs including targeted antisense RNAs and bended oligonucleotides. These, however, do not appear to be as effective as 5-Aza or 5-Aza2d. Another promising and as-yet-unrealized approach is to target methyl binding proteins. These are often found in larger complexes and may invoke the spreading of methylation from one locus to the next and transmission of methylated status from mother to daughter cells. By designing small-molecule inhibitors to methyl binding proteins, one may be able to prevent recognition and spread of methylated cytosines across replication.

4.2.2 HDAC Inhibitors

The recognition that heterochromatin is profoundly hypoacetylated led to the hypothesis that deacetylase inhibitors may be used to reactivate silenced genes. Historically, HDAC inhibitors were identified

in screens for chemicals that induce differentiation or inhibit cell cycle in tumor cells. These chemicals such as Trichostatin A (TSA) and sodium-*N*-butyrate (butyrate) induce hyperacetylation in cells concomitant with effects on cell-cycle progression. Trichostatin A causes cell-cycle arrest in either G1 or G2 and inhibits differentiation of the neuronal cell line PC12. Furthermore, butyrate also causes cell-cycle inhibition in culture and has been shown to suppress colon tumors in mice. Conversely, HDAC activity can be important in mediating cell-cycle inhibition as in the case of Rb that requires HDACs to inhibit E2F mediation of cell-cycle entry into S-phase.

Inhibiting HDAC activity can relieve repression on certain tumor suppressor promoters in cell culture model systems. Suberoylanilide hydroxyamic acid (SAHA) is in the same class of TSA and inhibits HDAC activity by blocking substrate access to the catalytic domain. Other hydroxiamic acids include *m*-carboxy cinnamic bishydroxamic acid (CBHA) and oxamflatin can be used at submicromolar concentrations and have longer half-lives than SAHA. Trapoxin A, apicidin, and depsipeptide (FR901228) are fungal metabolites that are tetrapeptides and irreversibly bind the catalytic site of HDACs. The cyclic hydroxyamic-acid containing peptide (CHAP) is a synthetic hybrid of tetrapeptides and hydroxyamic acids. Several analogs of CHAP have been tested for activity and have reversible inhibition at nanomolar concentrations. Interestingly, CHAP molecules also have specificity toward HDAC1 and HDAC4 more so than HDAC6. Preclinical studies using mice have proved exciting for butyrates, SAHA, and valproic acid and several HDAC inhibitor drugs such as phenylbutyrate and despeptide have proceeded to clinical trials with encouraging results. Because many DNA methyltransferase complexes also contain HDACs, HDAC inhibitors in combination with methyltransferase inhibitors have been or are being developed as one potential method of preventing the spreading of hypermethylated DNA in tumor cells.

Gene expression analysis following HDAC inhibitor treatments in cell lines indicated less than 10% change in gene expression profile. Although almost all HDAC inhibitors induce p21 and downregulate cyclins A and D and hypophosphorylation of Rb, it may be that HDAC inhibitors work as antitumor agents by their ability to block the cell cycle and induce apoptosis independently of chromatin modification and gene expression. It is possible that there is a critical role for HDACs in other posttranslational modifications of critical proteins in the cell cycle. There are approximately 17 members of the HDAC family with putative HDAC activity; however, only the class 1 HDACs are found in known protein complexes related to transcriptional repression. Because of the broad specificity of HDAC inhibitors in mediating cell-cycle inhibition and apoptosis, it remains to be seen whether individual HDACs are more involved than others. Development of HDAC inhibitors with subtype specificity will allow research to narrow the scope of inhibitor targets important in antitumor effects and from this knowledge produce better and better drugs.

5 Conclusions

In 2003, 50 years after the discovery of the double helix and 2 years after the successful sequencing on the human genome,

it is clear that DNA represents but the initial layer of genetic information. Superimposed on this beautiful structure are the instructions for its packaging into chromatin and specific epigenetic marks on the resultant DNA and histones. The importance of epigenetic changes in cancer are now well accepted on the basis of a broad spectrum of studies utilizing human and animal cell lines, animal models, and human tumors. The application of mechanistic principles to the functions of the RNA and protein factors so far identified represent a significant avenue for research on therapeutic interventions in cancer.

Keywords

Drosophila melanogaster
The vinegar fly (commonly referred to by the misnomer, fruit fly) first systematically studied in 1910 by Morgan and coworkers and arguably still the best-understood multicellular animal from both a genetic and molecular biological perspective.

Epithelium
A layer of polarized cells that are held together by cell-to-cell adhesions and are bounded basally by extracellular matrix.

Extracellular Matrix (ECM)
A network of macromolecules that resides outside of cells and is comprised largely of proteins and polysaccharides that are organized into a meshwork. The ECM interacts with nearby cells via specific transmembrane proteins present in the plasma membrane of these cells.

Metazoa
Animals whose bodies consist of many cells and that pass through embryonic stages of development. Distinct from protozoa, which are unicellular. Sponges, although multicellular, are sometimes classified separately as parazoa, since they contain no mesoderm and have no true organ systems.

Morphogenesis
During development, regeneration, or wound healing, the establishment of form and structure from simple, relatively undifferentiated cells, through cell movement, shape change, migration, differentiation, and programmed cell death.

An epithelium is a layer of polarized cells that are tightly bound together by a variety of junctional complexes and are connected to the extracellular matrix (ECM). Transmembrane proteins link the junctional complexes and the basal ECM to the cytoplasmic signal transduction machinery and the cytoskeleton of the epithelial cells. During development, epithelia are converted from simple two-dimensional sheets into complex, three-dimensional configurations in order to form tissues and organs. These morphogenetic changes are regulated in time and in space and are accompanied by differentiation of the cells within the epithelia into distinct identities. Epithelial morphogenesis is orchestrated by a variety of signaling molecules and transcription factors that coordinate cell shape changes, rearrangement, and migration. Much of the initial understanding of epithelial organization was derived from studies carried out on cultured vertebrate cells or tissues. More recently, genetic analyses in *Drosophila melanogaster* have complemented cell biological approaches and have provided insights into the spatial and temporal regulation of epithelial morphogenesis during development.

1 Epithelial Architecture

Epithelial cells have well-organized connections with neighboring cells and with the ECM. Cell adhesion proteins play a role in the maintenance of cell–cell and cell–ECM contacts as well as in transduction of extracellular signals into and out of epithelial cells. Cell adhesion complexes are made up of three classes of proteins – cell adhesion receptors, ECM proteins, and the cytoplasmic plaque proteins – many of which are conserved in all metazoa. The cell adhesion receptors are usually transmembrane glycoproteins that determine the specificity of cell–cell or cell–ECM interactions by interacting with proteins of the ECM or with other adhesion receptors in nearby cells. Several superfamilies of proteins fall into this category, including cadherins and integrins. ECM proteins are large glycoproteins including collagens, laminins, and fibronectins. These assemble into complex fibrils or other arrays that interact with cell adhesion receptors and thus with the cell surface. The cytoplasmic plaque proteins, such as catenins, are a link between adhesion receptors and the cytoplasmic signal transduction machinery as well as the cytoskeleton. The plaque proteins thus function to transduce signals from the adhesion complexes into the cell.

1.1 Cell–cell Junctions

While many of the molecular players are conserved, the ultrastructure of vertebrate and invertebrate junctional complexes and their location relative to the apicobasal cellular axis differ to some extent. Invertebrate epithelia have two types of junctions – adherens junctions and septate junctions – while three types of vertebrate junctional complexes have been described – tight junctions, desmosomes, and adherens junctions (Fig. 1).

Both vertebrate and invertebrate adherens junctions have cadherins as their major adhesion receptors. In epithelia, the adhesion receptor, E-cadherin, binds β-catenin. In turn, β-catenin binds α-catenin and α-catenin associates with the F-actin cytoskeleton (Fig. 2). In *Drosophila*, the most studied adherens junction is the zonula adherens, a beltlike structure localized at the apico-lateral region of epithelial cells, which contains DE-cadherin, the *Drosophila* homolog of E-cadherin, as well as α- and β-catenin. Adherens junctions are particularly prevalent in epithelia that experience strong contractile forces at their apices, as during invagination of sheets during normal development or wound healing.

Desmosomes are comprised of desmogleins and desmocollins, members of the cadherin superfamily that are linked to the cytoplasm by desmoplakins, plakoglobin (γ-catenin), and other cytoplasmic plaque proteins. Plakoglobin is a close homolog of β-catenin and fulfils some of the same functions. Desmosomes are linked to the intermediate filaments of the cytoskeleton (Fig. 1), creating a network that strengthens the cell. The desmosomal intermediate filament complex is particularly important in tissues that have to absorb high levels of mechanical stress. No intermediate filaments or desmosomes have been found in *Drosophila* or other invertebrates.

Tight or ''occluding'' junctions are found at the boundary between apical and basolateral cell surfaces (Fig. 1). They function to form a permeability barrier between the apical and basal sides of an epithelium, thus creating separate physiological compartments within a tissue or organ.

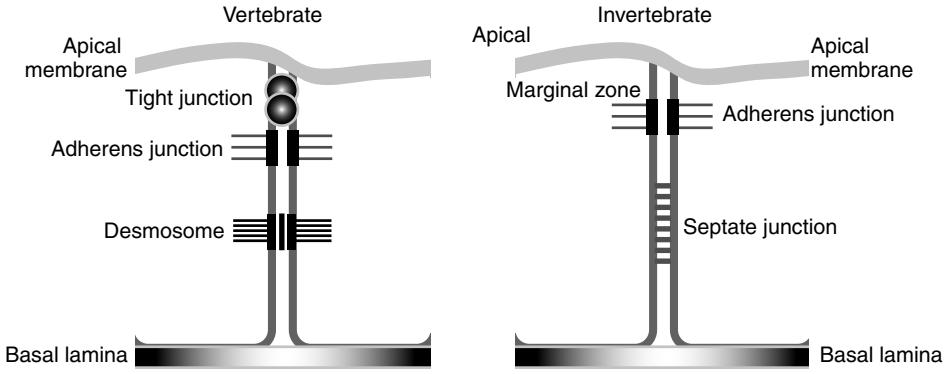

Fig. 1 Comparison of vertebrate and invertebrate cell junctions. (a) Vertebrates have three types of morphologically distinguishable junctions (from apical to basal: tight junctions, adherens junctions, and desmosomes) while *Drosophila* and other invertebrates (b) have two morphologically distinguishable junctions (from apical to basal: adherens junctions and septate junctions). At the molecular level, the adherens junctions of vertebrates and invertebrates are homologous. Homologs of vertebrate tight junction proteins are found in the *Drosophila* marginal zone. In invertebrates, septate junctions fulfil the role of tight junctions in controlling paracellular transport and gating functions. Desmosomes are unique to vertebrates both morphologically and in terms of molecular components. The fibers shown attached to the adherens junctions are F-actin while the fibers attached to the desmosomes are intermediate filaments. Figure based on Muller, H.A. (2000) Genetic control of epithelial cell polarity: lessons from Drosophila, *Dev. Dyn.* **218**, 52–67.

A major component of tight junctions is occludin, a transmembrane protein that contacts cytoplasmic plaque proteins such as zonula occludens protein-1 (ZO-1) and ZO-2, and the ECM. No convincing *Drosophila* occludin homologs have been found. However, *Drosophila* has two genes that encode proteins similar to mammalian claudin – another component of the tight junctions – as well as a homolog of mammalian ZO-1, known as *Polychaetoid*. Furthermore, the homologs of several tight junction proteins (e.g. Polychaetoid, Bazooka) localize to the marginal zone in *Drosophila*, suggesting that the invertebrate marginal zone may share some functions with vertebrate tight junctions. Functionally, but not locationally, tight junctions are similar to *Drosophila* septate junctions in that both control paracellular transport or gating functions.

1.2 Cell–ECM Contacts

Most cell–ECM adhesions share two features: they are mediated by integrins and they interact with the actin cytoskeleton inside the cell. The extracellular ligands that anchor these adhesions include fibronectin, vibronectin, and various collagens. The cells are attached to the collagen-rich interstitial matrix or to the basement membrane, a specialized structure that covers the basal surface of all epithelia. The basement membrane is formed from two layers: the basal lamina and the reticular lamina. The former is closer to the

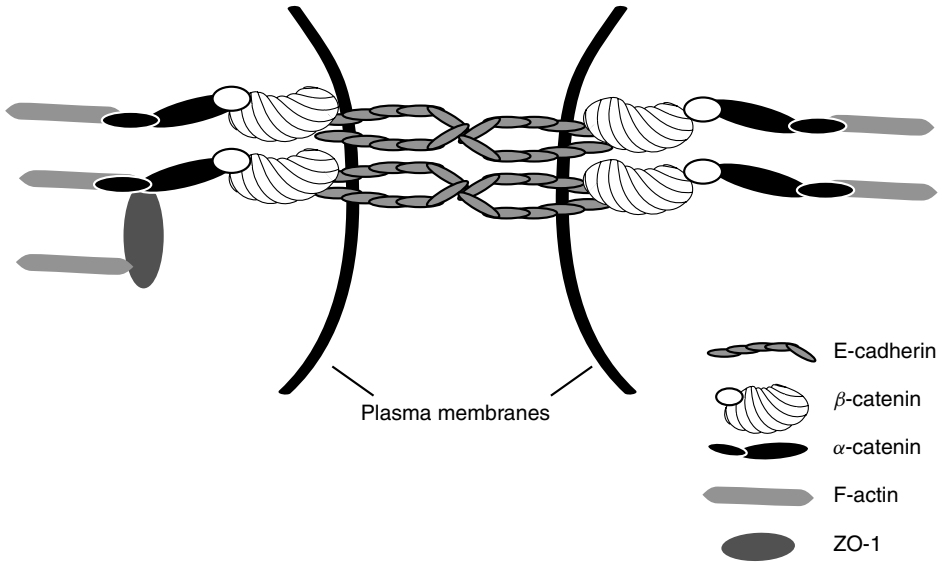

Fig. 2 A simplified adherens junction. The extracellular domain of E-cadherin dimerizes and interacts in a calcium-dependent manner with E-cadherin on neighboring cells. The distalmost segment of the cytoplasmic tail of E-cadherin interacts with β-catenin. α-catenin binds directly to F-actin and to β-catenin, thus linking the transmembrane adhesion receptor to the cytoskeleton. Additionally, α-catenin can bind to proteins such as ZO-1, which are components of tight junctions in vertebrates but are localized to the marginal zone in invertebrates such as *Drosophila*. Figure based on Vasioukhin, V., Fuchs, E. (2001) Actin dynamics and cell–cell adhesion in epithelia, *Curr. Opin. Cell Biol.* **13**, 76–84.

cell and is comprised of glycoproteins such as collagen type IV, laminin, and fibronectin, as well as proteoglycans. The reticular lamina is produced by fibroblasts and contains fibrillar collagens. The molecules that compose the basal lamina are well conserved among metazoa. *Drosophila* has two type IV collagens and four laminins as well as homologs of the glycoprotein nidogen/entactin and the proteoglycan perlecan.

Integrins are heterodimeric transmembrane proteins, composed of α- and β-subunits, whose extracellular domains interact with the ECM while their cytoplasmic tails interact with plaque proteins. The adhesiveness of the extracellular domains of integrin heterodimers is controlled by binding events in the cytoplasmic tails that trigger conformational changes across the plasma membrane (signaling "from the inside to the outside"). Reciprocally, ligand binding to the extracellular domains can trigger an intracellular signal (signaling "from the outside to the inside"). $\alpha\beta$ heterodimeric integrin receptors are found from sponges to mammals. *Drosophila* has two β- and five α-integrin subunits, including αPS1 and αPS2.

Focal adhesions are flat and elongated structures, usually found in the peripheral cytoplasm of cells, which are bound to integrin tails on the one hand and actin filaments on the other (Fig. 3). Focal adhesions comprise a multiprotein plaque that contains vinculin, talin, and paxillin,

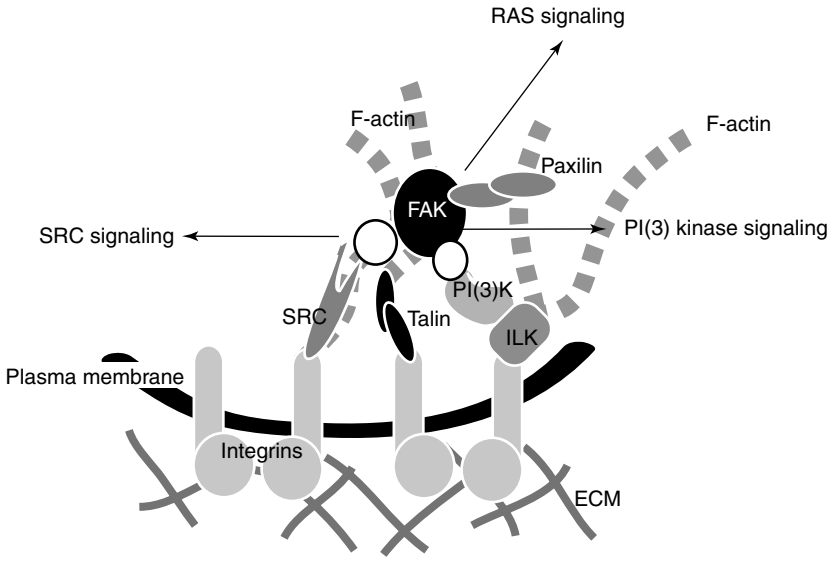

Fig. 3 Signaling and cytoskeletal complexes in focal adhesions. Integrins interact with the extracellular matrix as well as with signaling proteins in the cytoplasm. These include ILK, talin, and SRC – which interact directly with the cytoplasmic tail of integrin – as well as FAK, PI(3) kinase, and paxillin, which interact indirectly. The signaling complexes interact with and regulate the F actin–based cytoskeleton. Figure based on Miranti, C.K., Brugge, J.S. (2002) Sensing the environment: a historical perspective on integrin signal transduction, *Nat. Cell Biol.* **4**, 83–90.

among other proteins. Integrin-associated molecules, such as focal adhesion kinase (FAK), integrin-linked kinase (ILK), or paxillin may bind indirectly to the cytoskeleton through other components of the submembrane plaque, thus regulating the formation or function of focal adhesions. The constituents of focal adhesions are conserved in *Drosophila*, which has genes encoding talin, vinculin, tensin, paxillin, FAK, and ILK.

Fibrillar adhesions are found further from the plasma membrane than focal adhesions. They are elongated dot-like structures that are associated with ECM fibrils, and are typically composed of fibronectin (ECM component), $\alpha_5\beta_1$ integrin (transmembrane receptor), and tensin (cytoplasmic component). In the presence of fibronectin, $\alpha_5\beta_1$ integrin translocates out of the focal adhesion, forming a fibrillar adhesion that promotes fibronectin fibrillogenesis. *Drosophila* does not have fibrillar collagens, any long fibrinogen or fibronectin, and thus lacks fibrillar adhesions.

1.3 Cell Polarity

Epithelial cells have a well-defined apical–basal polarity (Fig. 1). Different domains along the apical–basal axis of an epithelial cell have distinct ECM, membrane, and submembrane cytoskeletal components. Many of these molecules (e.g. cadherins, catenins, and integrins) were first identified in biochemical or

cell biological studies in vertebrates and were subsequently shown to be conserved in metazoa. Along with their role in forming cell–cell and cell–ECM junctions, these proteins are crucial for cell polarity. For example, mutations in *Drosophila* genes such as *armadillo* (β-catenin), *shotgun* (DE-cadherin), and *karst* (β_{Heavy}- or β_{H}-spectrin) lead to defects in the establishment or maintenance of the adherens junctions and of epithelial polarity. Cell–ECM attachments are also important in defining the structural and functional apical–basal polarity of epithelial cells. For example, the E3 and E8 domains of laminin-1 can polarize mammary gland luminal epithelial cells in an α_6 integrin-dependent manner and reconstituted basement membrane can direct cultured mouse pre-Sertoli cells to develop into a polarized epithelium.

Several proteins that play a role in epithelial polarity were first identified on the basis of epithelial defects in *Drosophila* mutants. For example, Crumbs (CRB) is an apically localized transmembrane protein that regulates epithelial polarity in *Drosophila*. Recruitment of Stardust (SDT) and Discs lost (DLT, a PDZ domain-containing protein) – two proteins that are essential for epithelial polarity – to the apical membrane of epithelial cells depends on interactions with the cytoplasmic tail of CRB while, in turn, apical localization of CRB depends on the SDT and DLT proteins.

PDZ domain-containing proteins, including the LAP (Leucine-rich- and PDZ domain-containing) subfamily, are involved in the determination and maintenance of apical–basal epithelial polarity. LAP proteins are thought to form a barrier that keeps apical determinants in the apical domain of epithelial cells. In addition, LAP proteins create and maintain polarity by transporting and anchoring binding partners to particular membrane domains. For example, the human homolog of *Drosophila discs large* (DLG), hDLG, binds kinesin-like motors that interact with the microtubule cytoskeleton to transport and localize binding partners to the membrane. Mutations in the *Caenorhabditis elegans let-413* LAP protein-encoding gene lead to abnormal epithelia with defective adherens junctions, which are mislocalized to more basolateral positions, and a disorganized actin cytoskeleton. Absence of the *Drosophila* LAP proteins Scribble and DLG leads to defects in apical–basal epithelial polarity and defective morphogenesis.

Members of the RHO family of small GTPases (CDC42, RAC1, and RHO), molecular switches that regulate cell signaling pathways and the organization of the actin cytoskeleton, have been implicated in maintaining polarity of epithelial cells. CDC42's role in epithelial apical–basal polarity is in the regulation of polarized transport of secretory vesicles as well as in the stabilization of adherens junctions. RAC1 is involved in the proper formation of tight junctions in epithelial cells. RHO plays an important role in adherens junction formation, intracellular targeting of proteins, and phosphorylation of catenins.

Maintenance of epithelial polarity is crucial for many aspects of epithelial function. For example, transmembrane adhesion molecules and receptors in the basolateral domain facilitate communication with other cells and with the ECM. The apical domain, in contrast, is not in permanent contact with other cells and, typically, faces either the body cavity or the lumen in the case of epithelial tubes. Tight junctions separate the apical and basal domains and are responsible

for lateral cell–cell adhesions as well as for creating a barrier that restricts diffusion of fluids and molecules through the epithelium. Thus, the different sides of an epithelium implement distinct cellular functions while interacting with and maintaining different extracellular environments. If apical–basal polarity fails, cell–cell and cell–ECM connections are affected and epithelial function and/or integrity is therefore compromised.

Interestingly, there is a close link between apical–basal polarity and growth control. Mutations in genes such as *Drosophila scribble, discs large*, and *lethal giant larvae*, which affect epithelial polarity as described above, have also been found to cause uncontrolled cell proliferation. Defects in apical–basal polarity probably cause these cells to lose cell–cell or cell–ECM connections, which in turn allows them to divide.

2
Cellular Basis of Epithelial Morphogenesis

2.1
Cell Adhesions and Signal Transduction

The epithelial shape changes and movements that occur during morphogenesis – as well as the functions of mature, differentiated epithelia – need to be coordinated in time and space. As described in Sect. 1 above, cell–cell and cell–ECM junctions include transmembrane receptors that are linked to the intracellular signaling apparatus. These junctions participate in signal transduction events that regulate cell adhesion, cell motility, and cell shape and thus are crucial for epithelial morphogenesis.

Adherens junctions (described in Sect. 1.1; see Fig. 1 and 2) play a key role in signal transduction within epithelia. The adherens junction component, β-catenin, has roles in cell adhesion, signal transduction, and transcriptional activation. For example, when the WG/WNT signaling pathway is inactive, free β-catenin is phosphorylated by glycogen synthase kinase (GSK) and axin, leading to ubiquitination and degradation of β-catenin. When WG/WNT binds to its receptor, Frizzled (FZ), the Dishevelled (DSH) protein inhibits phosphorylation of β-catenin by GSK. Unphosphorylated β-catenin is stable and accumulates in the nucleus where, together with TCF, it transactivates target genes such as *cyclin D1* and *myc*.

Integrins mediate signal transduction into epithelial cells via focal adhesions, giant membrane–associated protein complexes that contain dozens of stably or transiently associated proteins (see Sect. 1.3 above). Ligand binding, integrin aggregation, and actin polymerization affect the recruitment of different proteins to focal adhesions. These adhesions are linked to webs of intracellular proteins, simultaneously affecting several signal transduction pathways (Fig. 3). For example, the EGFR (epidermal growth factor receptor), PDGFR (platelet-derived GFR), and VEGFR (vascular endothelial GFR) can be activated by focal adhesions, specifically by integrins, thus triggering a RAS-RAF-MAP kinase (MAPK) cytoplasmic signal transduction cascade.

2.2
The Actin-based Cytoskeleton

The assembly and disassembly of filamentous actin (F-actin), a major constituent of the cytoskeleton of all eukaryotic cells, is highly regulated (Fig. 4). For example, proteins function to sequester actin monomers to prevent polymerization

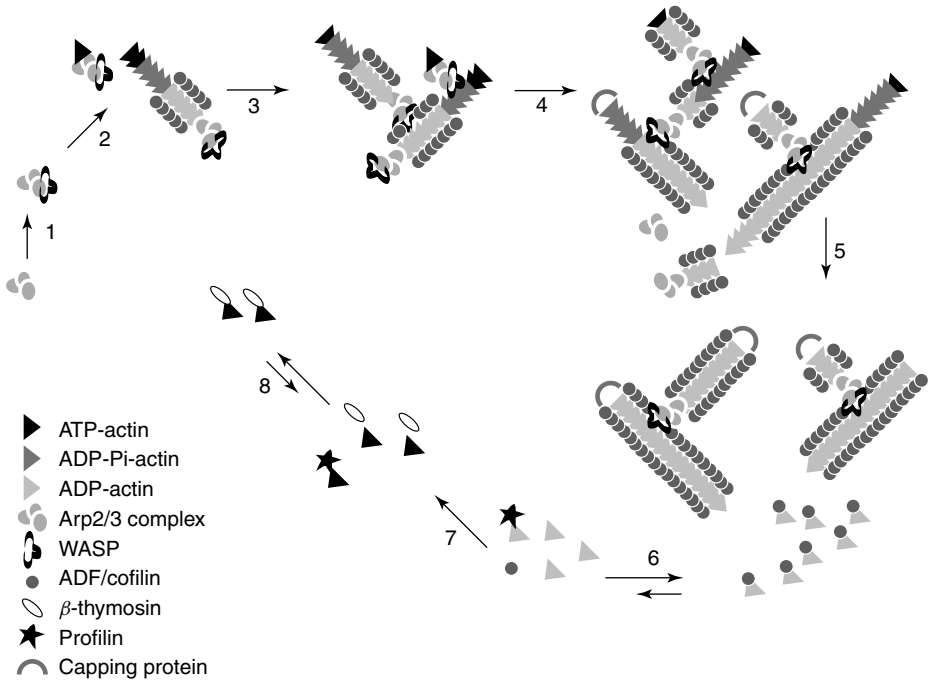

Fig. 4 Actin dynamics. The actin network in the leading edge of cells can promote formation of lamellipodia (shown here) or filopodia via regulated polymerization and depolymerization of F-actin by actin-binding proteins. (1) The Arp2/3 complex is activated upon binding to WASP, which is activated by the small GTPase, CDC42. (2) The active Arp2/3-WASP complex nucleates actin filaments at the free (pointed) end or (3) binds to the side of the filament and nucleates a branch. Reduced dissociation rates of ADP-P_i from actin result in growth of filaments. (4) Capping of the barbed ends of the actin filaments prevents further elongation. (5) ADF/cofilin enhances depolymerization of ADP-actin from the free filament end. (6) The ADF/cofilin/ADP-actin complex that dissociates from the filament is in equilibrium with ADF/cofilin and ADP-actin monomers. (7) Nucleotide exchange on actin monomers is a slow process that is enhanced by profilin and inhibited by ADF/cofilin. (8) ATP-actin monomers are sequestered by β-thymosins to prevent spontaneous nucleation, while simultaneously providing a pool of ATP-actin for filament assembly. Figure redrawn from Chen, H., Bernstein, B.W., Bamburg, J.R. (2000) Regulating actin-filament dynamics *in vivo*, *Trends Biochem. Sci.* **25**, 19–23, with permission from Dr. J. Bamburg.

(β-thymosins), to enhance nucleotide exchange (profilin), to split F-actin to generate more ends (gelsolin, ADF/cofilin also known as the AC family of proteins), or to create a cap at the end of the filament, resulting either in filament growth (Arp2/3 complex) or in enhanced subunit dissociation (gelsolin). Signals that regulate actin dynamics are transmitted through receptor tyrosine kinases, the RHO-family GTPases, and G protein–coupled receptors. These molecules receive and transmit signals that lead the WASP (Wiskott-Aldrich Syndrome protein)-Arp2/3 complex to nucleate F-actin assembly. Both the

molecular components and the regulatory processes of actin dynamics are conserved between *Drosophila* and mammals.

Dynamic changes in F-actin control cell–cell adhesion in epithelia. For example, as described above (Sect. 1.1), in epithelial cells, the adherens junction proteins E-cadherin and β-catenin are linked to the actin cytoskeleton via α-catenin. If the actin cytoskeleton is disrupted or catenin function is lost, intercellular adhesions are not formed or are not maintained. Moreover, the small GTPases, RHO and RAC, function as F-actin organizers and are required for adherens junction formation.

Many morphogenetic processes during development of diverse organisms utilize actin-dependent cytoskeletal extensions to sense the extracellular environment and to transmit signals over long distances. For example, neurons extend filopodia for axon-guidance while, during embryonic dorsal closure, the leading edge cells of the epidermis extend filopodia that contact the extra-embryonic amnioserosa as well as the leading edge cells on the opposite side of the embryo (see Sect. 3.1 below for details).

In cultured epithelial cells, prior to cell–cell contact, actin forms marginal dynamic bundles that undergo rearward flow in a myosin II-dependent manner. Actin polymerization at the free, leading edge of the cell drives lamellipodial protrusions, resulting in the establishment of contacts with neighboring cells. Once the cells contact each other, the rearward actin flow ceases and adherens junction components, such as E-cadherin, accumulate at the site of contact. Actin arcs then form at the edges of the region of cell–cell contact. Subsequently, during the lateral expansion of the initial contact, old marginal actin bundles disassemble and new ones are formed, thus strengthening cell–cell adhesions. If cell–cell contacts are broken *in vitro*, then F-actin is reduced in adherens junctions, and proteins such as α- and β-catenin are lost from the junctions. Thus, establishment and maintenance of epithelial cell–cell contacts in culture requires the coordinated function of actin-filament bundles, myosin II, microtubules, and cell adhesion proteins.

As discussed in Sect. 2.1, proper cytoskeletal organization is necessary for signal transduction into epithelial cells as well as for ECM-to-cell communication. For example, integrin β-subunits regulate the structure of the actin cytoskeleton as well as the activities of the small GTPases, RHO, and RAC. Integrin attachment to the ECM is sufficient for the induction of lamellipodia, filopodia, and focal adhesions through RHO activation. Overexpression of β_3 integrin in hamster ovary cells enhances RHO activity and stress fiber formation (stress fibers are F-actin bundles in which the fibers are loosely cross-linked), whereas overexpression of $\beta 1$ integrin increases RAC and Jun N-terminal kinase (JNK) activity and formation of lamellipodia in which the F-actin fibers form a gel-like network. These results suggest that distinct integrins regulate different processes in epithelial cells by differentially regulating molecules such as RHO and RAC.

Cells also use integrin/actin complexes as mechanosensors to probe the rigidity of the extracellular environment, thus modulating cell–ECM adhesion and triggering signaling events. For example, a local mechanical force induces clustering of integrin molecules, thus leading to the formation of a focal complex at the site of plasma membrane deformation (focal complexes are $\sim$1 µm dotlike adhesions found at the cell periphery,

which are enriched in actin filaments and initiate specific signals). Focal complexes can evolve into stable focal adhesions; both internal and external forces enhance such a conversion. The molecular regulation of cell–ECM contacts and mechanosensation mechanisms are poorly understood. Insights will derive from cell culture on three-dimensional ECM, rather than the more traditional two-dimensional culture methods. *In vivo* studies using high-resolution microscopy in live organisms such as *Drosophila* will also shed light on the molecular regulation of cell–ECM interactions and the transduction of external cues into changes in cytoskeletal structure and function.

Among the cytoskeletal proteins that play a role in epithelial structure and function, spectrin plays a particularly crucial role. The spectrin protein, composed of two α- and two β-subunits, cross-links F-actin. Different spectrin isoforms are found associated with the basolateral versus the apical region of epithelial cells. For example, *Drosophila* has three spectrin subunits, α, β, and β_H. Each of the two β-subunits heterodimerizes with α-spectrin, and the $\alpha\beta$ and $\alpha\beta_H$ heterodimers show nonoverlapping distributions in epithelial cells; $\alpha\beta$-spectrin localizes to the basolateral membrane whereas $\alpha\beta_{\mathrm{H}}$-spectrin is apically enriched in the marginal zone. Mutational analyses have shown that, during *Drosophila* development, $\alpha\beta_{\mathrm{H}}$-spectrin is required for the differentiation of the apical membrane, and that β-spectrin functions independent of α-spectrin in differentiation of the basolateral membrane domain. When β_{H}-spectrin is absent or nonfunctional, in *karst* mutant embryos, the adherens junctions of the ovarian follicle epithelial cells are fragmented, and the cells fail to constrict apically, suggesting a requirement for β_{H}-spectrin in regulation and maintenance of the adherens junctions.

3
Regulation of Epithelial Morphogenesis: Lessons from *Drosophila*

During epithelial morphogenesis, the diverse cellular processes described above have to be coordinated. This is accomplished by exploiting the ability of epithelial cells to respond to extracellular cues and to transduce such signals into changes in cell shape and behavior. Here we consider specific morphogenetic processes in *Drosophila* and describe how genetic and molecular analyses have led to insights into how epithelial morphogenesis is coordinated in the context of a complex, developing organism.

3.1
Epithelial Sheet Movement and Fusion: Dorsal Closure

Following germ-band retraction of the *Drosophila* embryo, a hole is left on the dorsal side of the embryo, where epidermis is absent (Fig. 5). This hole is covered by the amnioserosa, an extraembryonic epithelium. Dorsal closure involves the dorsalward migration of lateral epidermis on both sides of the embryo such that the leading edges of the left and right epidermal epithelia meet and fuse at the dorsal midline, completely covering the amnioserosa and sealing the epidermis around the embryo (Fig. 5). There is little or no cell division or cell rearrangement in the epidermal epithelium during dorsal closure. Almost all of the morphogenetic process is thus accomplished through coordinated cell shape changes within the epithelium; cells lengthen along

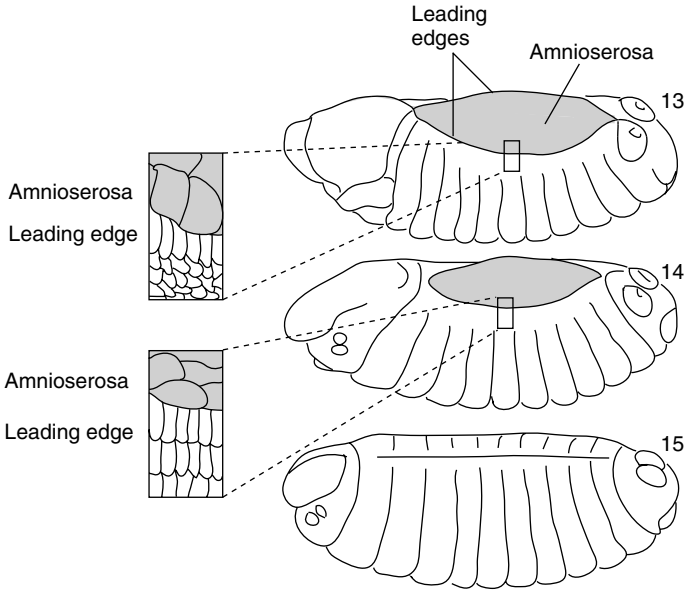

Fig. 5 Dorsal closure in *Drosophila*. Three stages of dorsal closure are shown: (top) initiation, (middle) spreading, and (bottom) suturing. Initiation is first visible in stage 13 embryos (9 to 10 h after fertilization, AF) as the rim of the dorsalmost epidermal cells, the leading edge cells, undergoes dorsoventral elongation. Subsequently, the more lateral epidermal cells also undergo progressive elongation, thus promoting spreading of the lateral epidermal epithelial sheets dorsally. Concomitant with this spreading, the amnioserosa cells (gray) contract across the dorsoventral axis of the embryo. This spreading phase lasts about 2 h, during embryonic stages 13 to 15. When the leading edges of the lateral epidermal sheets reach the dorsal midline, cells have elongated three- to fourfold. During suturing, the sheets meet at the dorsal midline and fuse in register, thus, completely enclosing the embryo within the epidermis. Figure based on Hartenstein, V. (1993) Atlas of *Drosophila* Development, Cold Spring Harbor Laboratory Press, Cold Spring Harbor and Noselli, S. (1998) JNK signaling and morphogenesis in *Drosophila*, *Trends Genet.* **14**, 33–38.

the dorsoventral and shorten along the anteroposterior axis of the embryo. Reciprocally, the amnioserosal epithelial cells shorten along the dorsoventral axis as the epidermal epithelium extends dorsally. Dorsal closure thus exemplifies how coordinated cell shape changes throughout epithelial sheets can drive morphogenesis.

The forces that drive the process of dorsal closure come from both the amnioserosa and the lateral epidermis. This was demonstrated by performing laser ablations of cells in the amnioserosa and/or of cells in the lateral epidermis; neither of these types of ablations inhibits dorsal closure but a combination of both does. A crucial component of the force-generation system is the F-actin/myosin-based "purse string" that is assembled at the apico-dorsal region of the epidermal

leading edge cells adjacent to the amnioserosa. Contraction of this purse string drives dorsalward movement of the epidermal sheet and eventual fusion at the dorsal midline. In myosin II (*zipper*) mutants, dorsal closure fails because the purse string is unable to contract.

Pivotal to the reorganization and contraction of the F actin–based cytoskeleton are RHO, RAC, and CDC42 (discussed in Sects. 1.3 and 2.2 above). Mutants or transgenic flies that express dominant negative versions of these small GTPases show defects in dorsal closure and in F-actin distribution.

Cell shape changes in the leading edge and more lateral epidermal cells are crucial for dorsal closure. These shape changes are coordinated through activity of the BMP/TGFβ-family ligand, DPP, WG/WNT, and JNK signaling. These signals direct the more lateral epidermal cells to change their shape and extend dorsally, in an F actin–dependent process.

Essential for dorsal closure is definition of the boundary between the epidermal leading edge cells and the amnioserosa since the purse string is assembled at this boundary. Recent data suggest that modulation of JNK signaling plays a crucial role in establishing or implementing this boundary. Initially, JNK signaling is present in both the amnioserosa and the epidermal leading edge cells. Prior to dorsal closure, however, JNK signaling is downregulated in the amnioserosa leading to a low/high JNK signaling boundary that coincides with where the purse string assembles. If JNK signaling is not downregulated in the amnioserosa, a high/high JNK signaling situation persists, no purse string is assembled and dorsal closure fails. Reciprocally, if JNK signaling is downregulated in both the amnioserosa and the leading edge cells, then a low/low situation pertains and, again, the purse string is disrupted and dorsal closure fails. Mutant situations in which the high/high situation is converted to a low/high one, lead to rescue of both the purse string and dorsal closure.

The actual zipping up or suturing at the dorsal midline (Fig. 5) is achieved by actin-based mechanisms. During dorsal closure, actin and nonmuscle myosin II accumulate at the leading edge where long and active filopodia form. Leading edge filopodia formation is dependent on the activity of small GTPases and JNK signaling. In order to stop epidermal sheet movement and allow in-register left–right leading edge fusion, filopodia must discriminate between the different segments of the embryo and JNK signaling must be downregulated. During suturing of the epithelial sheets at the dorsal midline, the filopodial contacts lead to the production of precursors of mature adherens junctions.

The low/high JNK signaling boundary may be required to trigger formation of filopodia by the leading edge cells as described above. Reciprocally, it has been proposed that contact of high JNK signaling cells (as when the filopodia from the left and right leading edge cells meet) serves as a ''stop'' signal that prevents further epithelial sheet movement. In mutants in which JNK signaling is not downregulated in the amnioserosa, a premature stop signal may be received and thus epithelial sheet movement never initiates.

It should be noted that actin-binding molecules such as profilin (see Sect. 2.2 above), encoded by *chickadee*, have been implicated in dorsal closure. Mutant *chickadee* embryos show disrupted actin filopodia similar to those found in embryos lacking JNK activity. This suggests that in the

leading edge cells, the JNK cascade drives the synthesis and/or activation of profilin, which is involved in the production of the filopodia required for dorsal closure.

There are extensive similarities between the epithelial sheet movements that occur during dorsal closure and those that occur during *C. elegans* ventral enclosure and mammalian wound healing. The mechanisms that have been identified as coordinating and directing epithelial sheet movement during dorsal closure are also likely to underlie epithelial sheet movement in these systems. For example, time lapse analysis of live *C. elegans* embryos during ventral enclosure has shown that ''leader'' cells have active filopodia, that α-catenin accumulates where opposing filopodia make contact, and that this is followed by the formation of mature adherens junctions between the cells that achieve contact. Similar filopodia and F actin–based purse strings have been seen in epithelial cells in culture and during wound healing.

3.2 Branching Morphogenesis and Epithelial Tube Formation: the Tracheal system

During morphogenesis of the *Drosophila* embryonic tracheal system, clusters of epithelial cells invaginate, branch, and migrate in the absence of cell division and cell death. The tracheal system develops from 20 clusters of epidermal cells, 10 each on the left and right surfaces of the embryo, each of which contain ~80 cells (Fig. 6). These clusters invaginate internally and then branch in a stereotypical manner, each giving rise

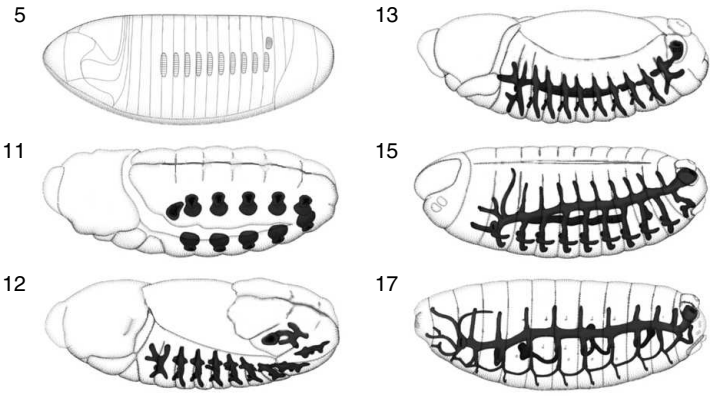

Fig. 6 Tracheal branching morphogenesis in *Drosophila*. The tracheal system develops from 20 placodes, 10 on the surface of each side of the embryo, that are conferred tracheal fate by stage 5 of embryogenesis (2 to 3 h AF). These clusters of cells divide twice to give rise to about 80 cells per placode. Invagination begins at stage 11 (5 to 7 h AF), followed by stereotypic primary branching at stage 12 (7 to 9 h AF). Fusion of specific branches occurs at stages 14 and 15 (10 to 13 h AF), giving a complex tubular system. Secondary and tertiary branching takes place respectively at stages 15 (11 to 13 h AF) and 17 (16 to 20 h AF). Figure modified from Hartenstein, V. (1993) Atlas of *Drosophila* Development, Cold Spring Harbor Laboratory Press, Cold Spring Harbor with permission from the publisher.

to five primary tracheal branches at stage 12 of embryogenesis. Specific tracheal cells elongate and then fuse to create continuous tubes whose lumen allows the passage of oxygen to all the tissues of the organism via secondary and tertiary (''terminal'') branches that form a complex tubular network by embryonic stage 17. The apical side of the tracheal epithelium faces the lumen while the basal side is bounded by a collagen IV- and laminin-rich basal lamina. A detailed description of the cellular and molecular mechanisms of tracheal development is available.

Tracheal cell fate is conferred by the basic-HLH transcription factor, Trachealess (TRH), and its binding-partner Tango. The POU-domain protein encoded by *drifter* interacts with TRH to induce tracheal fates. The tracheal clusters are then subpatterned through FGF and DPP signaling; dorsal and lateral branches depend on DPP while ventral branches are determined by FGF.

Primary branching morphogenesis is controlled by one of the two *Drosophila* FGF receptor homologs, breathless (BTL) and its ligand, branchless (BNL). Just before a trachea branches, patches of BNL expression occur in specific clusters of epidermal cells near the tracheal sac. Binding of BNL to BTL induces a RAS-RAF-MAPK signal transduction cascade, resulting in cytoskeletal changes that direct the formation of buds that will, in due course, become branches. Recent work utilizing *in vivo* imaging has shown that DPP and FGF regulate different cellular events in tracheal branching morphogenesis. FGF signaling is required for the formation of filopodia while DPP is important for branch outgrowth. The FGF pathway acts together with cell surface proteins that control cell–cell and cell–ECM interactions during tracheal branching. For example, expression of PS1 integrin (αPS1βPS) specifically in the middle part of the developing tracheal placodes, and PS2 integrin (αPS2βPS) in the visceral mesoderm, is necessary for visceral branch migration. FGF signaling also induces secondary branching genes, including *pointed*, which encodes an ETS domain transcription factor, and *sprouty*, which encodes an inhibitor of branching. Interestingly, the FGF and BMP/TGFβ pathways also function in branching morphogenesis during mammalian lung development.

Specific genes such as *escargot*, which encodes a zinc-finger transcription factor, control fusion of the tracheal tubes by regulating cell shape changes and DE-cadherin production. Before fusion takes place, BTL is activated in a group of ''leading'' cells at the tip of the branch. The Notch–Delta pathway functions via lateral inhibition to distinguish the ''fusion'' cells from ''nonfusion'' cells within the leading cell group. In fusion cells, RHOA and the plakin, Short stop, are required for DE cadherin–dependent apical localization of the cytoskeletal structures that participate in the fusion event.

Terminal branches are long, thin cytoplasmic extensions, that form at the end of embryogenesis and later ramify non-stereotypically in response to low oxygen levels. Cell fate is determined by Notch (N), which is expressed in terminal cells and inhibits other cells from adopting a terminal fate. Terminal branching is guided by levels of oxygen, and by the BNL pathway together with Blistered (also known as Pruned), the serum-response factor homolog in *Drosophila*. Terminal extensions resemble F actin–based filopodia observed in other tissues during morphogenesis and serve to sense the environment as well as to transmit signals to nonneighboring cells.

As epithelia undergo morphogenesis, cell–cell and cell–ECM interactions must be modulated to allow shape changes and rearrangements relative to their neighbors without loss of epithelial integrity. Recent analyses have shown that the Hindsight (HNT) zinc-finger nuclear protein regulates tracheal epithelial integrity during the later stages of branching morphogenesis. In *hindsight* mutants, while primary and secondary branching occurs normally and fusion events initiate, the tracheal epithelium subsequently loses its integrity resulting in epithelial sacs. In *hindsight* mutants, the basal lamina that surrounds the tracheal tubes is abnormal, with an irregular distribution of both collagen IV and laminin, implicating the basal lamina in maintenance of epithelial integrity during branching morphogenesis.

3.3 Epithelial Patterning and Morphogenesis at Single-cell Resolution: the Retina

In *Drosophila*, the adult compound eye comprises an array of approximately 800 unit eyes or ommatidia (Fig. 7). The precise external hexagonal arrangement of these facets reflects a repetitive underlying cellular lattice. Each ommatidium is a stereotypical 19-cell assembly of eight

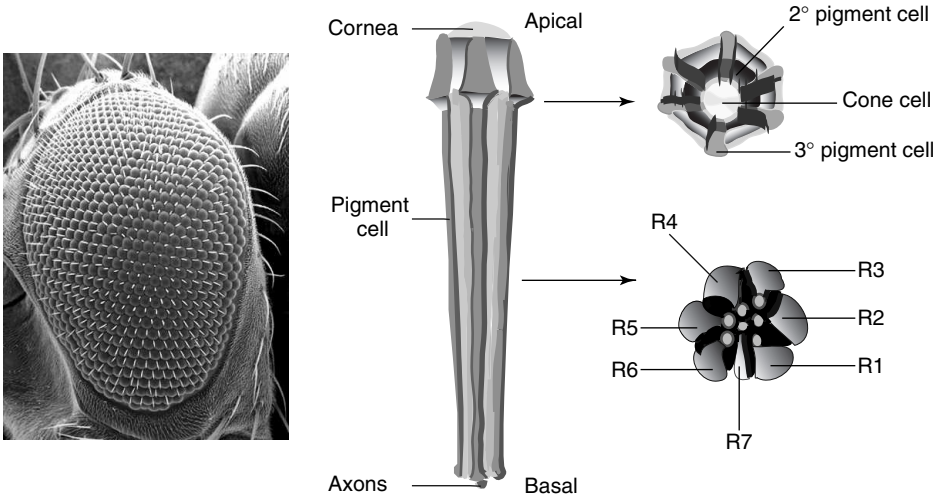

Fig. 7 The adult retina of *Drosophila*. The eye is comprised of about 800 small unit eyes or ommatidia packed in a hexagonal array, with mechanosensory bristles at alternate interommatidial vertices (a scanning electron micrograph is shown on the left). A single ommatidium is shown in longitudinal profile (middle) and cross-sectional views (right). Apically, the cornea is secreted by the cone cells, which extend dorsally and close over the top of the photoreceptor (R) cells during the pupal period. Primary and secondary pigment cells surround the cone and R-cells. At the base of the ommatidium, the cone and pigment cell feet meet to form a cone cell plate and fenestrated basement membrane through which the axons pass. The rhabdomeres of the outer R-cells (R1 to 6) are arranged in a stereotypical trapezoidal pattern around the inner R-cell (R7; the R8 cell is not visible in this plane of section) (lower right). Pigment cells are omitted from the lower cross-section for clarity. Figure based on Wolff, T., Ready, D. F. (1993) Pattern Formation in the *Drosophila* Retina, in: *The Development of Drosophila melanogaster*, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, pp. 1277–1325.

photoreceptors (R-cells) and 11 accessory cells. R-cells are of three distinct classes: the R1–R6 class that surrounds two central photoreceptors; the distally located central R7 cell and, below it, the more proximally positioned central R8 cell. Each R-cell may be identified by virtue of its photosensitive rhabdomere, which is a dense microvillar extension that extends along the entire length of the ommatidial column. Above the R-cells are four cone cells surrounded by two primary pigment cells. Additional pigment cells form a mesh that encases the core of R-cells, cone cells, and primary pigment cells, and creates a honeycomb-like matrix. Small mechanosensory bristles project from alternate vertices of each ommatidium. At the base of the retina, the cone cells meet to form the cone cell plate; below this plate the feet of some of the pigment cells create the fenestrated membrane, which is a specialized basement membrane. Actin stress fibers anchor the pigment cell feet to specialized rings of ECM material.

The *Drosophila* eye is one of the most intensively studied of all developing organs, in part because its repetitive structure and external location facilitate identification of mutant phenotypes and in part because analyses of mutant versus wild-type tissue in genetic chimeras (''mosaics'') is possible at single-cell resolution. Thus, cell fate specification and morphogenesis within the retinal epithelium are understood in remarkable detail. The description of retinal morphogenesis presented here will, thus, be more detailed than that presented above for dorsal closure and tracheal branching, to emphasize how individual cell types behave.

Cells giving rise to the fly eye are first set aside in the embryo when an ectodermal invagination forms the specialized retinal epithelium known as the eye disc. By the third instar larval stage, the disc has become a two-layered sac composed of columnar epithelium on one side (the disc proper) and a squamous epithelium on the other (the peripodial epithelium). Beginning in the mid-third instar larva, a dorsoventral groove known as the morphogenetic furrow sweeps across the eye disc from the posterior to the anterior side leaving organized clusters of R-precursor cells in its wake. Initiation of the furrow at the posterior margin of the disc is under the concerted control of the secreted morphogens Hedgehog (HH), DPP, and WG/WNT and also requires the EGFR and N-receptor mediated signaling cascades. The developing clusters posterior to the furrow produce HH, which signals to more anterior cells and pushes the furrow across the disc. Morphogenetic events in the furrow are a prelude to subsequent R-cell precursor specification posterior to the furrow. Anterior to the furrow, the unpatterned cells are dividing randomly and they have large apical profiles. Within the furrow, cells stop dividing and synchronize in G_1 of the cell cycle. DPP is expressed in the furrow and it coordinates this cell cycle transition with the movement of the furrow across the disc. Changes in cell shape – a 15-fold reduction in the apical profile and significant cell shortening along the apical–basal axis – are accompanied by the basal migration of the nuclei and cell bodies. This cell shape transformation is caused by the constriction of apical actin cytoskeletal rings and it results in the concentration of apically localized receptors and ligands involved in pattern formation in the furrow. The proteins Act up and Chickadee/profilin regulate the actin polymerization necessary for this cell shape change. Cell shape changes, but not nuclear movement, appear to be coordinated with the timing of photoreceptor

differentiation as *act up* and *chickadee* mutants display premature differentiation.

In the middle of the furrow, cells aggregate to form equidistant clusters of 20 or so cells. These stereotypical ''rosettes'' are the rudiments of future ommatidia and they probably overlap with the so-called intermediate clusters, which express the bHLH transcription factors Atonal (ATO) and Daughterless (DA). The EGFR, the secreted fibrinogen-like Scabrous (SCA) protein, and the receptor/ligand pair N/Delta have all been implicated in a lateral inhibition process whereby rosette cells emit an inhibitory signal, preventing their near-neighbor cells from becoming part of the intermediate group of cells, and an inductive signal to determine the R8 precursor cell. This signal is thought to give rise to the periodic spacing of the rosettes and to whittle the ATO/DA expression down to just one cell, which will later become the R8 cell.

Every two hours, a new row of R precursor–cell clusters emerges from the furrow (Fig. 8). Each rosette transforms into a rearward-pointing curve of 7 to 9 cells – called an arc – and then, typically, seven of these cells zipper shut expelling all excess cells anteriorly. The definitive five-cell precluster containing the R8, R2, R5, R3, and R4 precursor cells forms as the R3 and R4 cells come to contact one another. In a mature larval eye disc, there are about 25 rows that exhibit progressive stages of ommatidial morphogenesis between the furrow and the posterior of the disc. Photoreceptor precursor cell subtype is specified sequentially; first R8 followed by R2/R5, then R3/R4, and then R1/R6. R7 is the final photoreceptor precursor cell to express neural antigens and the last one to differentiate. A series of cell-autonomously acting transcription factors together with secreted growth factors is responsible for establishing the unique identity of each photoreceptor cell.

The array of ommatidia is organized into two mirror-image fields divided by a dorsoventral midline, called the equator. This pattern requires a 90° rotation of the ommatidial clusters behind the furrow in the larval eye disc (Fig. 8). Two vectorial signals are necessary to regulate the direction and extent of rotation as well as a rearrangement of the cells in the early symmetric cluster to create the mature asymmetric cluster. One signal is emitted by cells in the morphogenetic furrow and includes the vesicular transport of SCA to more posterior cells using an actin-mediated mechanism. The other signal involves molecules important for tissue polarity in other epithelia. These include components of the WNT/FZ signaling pathway, namely, the interacting cytoplasmic proteins DSH and Prickle-Spiny Legs; the atypical cadherin, Flamingo/Starry night; the RHOA GTPase, and its kinase dROK, the kinase Misshapen; and a JNK cascade that sets up the distinction between R3 and R4 fates by regulating the level of the Puckered phosphatase and Delta in these cells. Other factors that regulate polarity include the zinc-finger transcription factor, HNT, which may do so by downregulating JNK signaling, and the novel four-pass transmembrane protein, Strabismus/van Gogh. It is not yet clear how the output of these signals controls planar polarity in the eye, but the rotation itself requires the serine/threonine protein kinase Nemo and the uncharacterized Roulette protein. It is likely that the cluster movements and changes in cell shape involve modifications of the cytoskeleton and the ECM, but so far, the only concrete link with these components is a requirement for the cadherins,

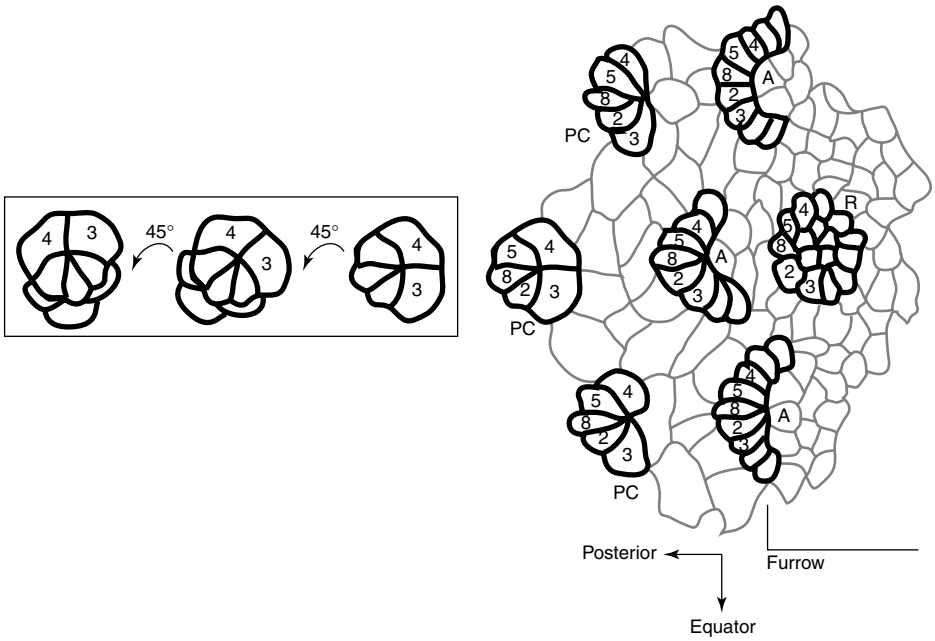

Fig. 8 Ommatidial cluster formation and rotation during *Drosophila* retinal morphogenesis. The diagram shows the apical profiles of the photoreceptor cell precursors (R2, 3, 4, 5, and 8) on the dorsal side of a third instar larval eye disc. Every two hours, another column of clusters is added anteriorly (on the right). In the furrow, clusters of 20 or so cells become ''rosettes'' (R). These open up anteriorly to form ''arcs'' (A). The arcs then zipper shut and expel cells on their anterior side to form the ''five-cell precluster'' (PC) The box on the left is a schematic (compressed over many columns) showing how ommatidial planar polarity is established in the eye disc. Initially, the symmetrical five-cell precluster is arranged so that the R3 precursor is closer to the equator than the R4 precursor. Subsequently, the cluster rotates 90° toward the equator. In its mature form (not shown here), mirror-image symmetry is broken to form a chiral ommatidium as the R4 cell loses contact with the R8 cell and moves to a more equatorial position to give the trapezoidal arrangement of the rhabdomeres seen in the adult ommatidium shown in Fig. 7. Figure based on Wolff, T., Ready, D. F. (1993) Pattern Formation in the *Drosophila* Retina, in: *The Development of Drosophila melanogaster*, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, pp. 1277–1325.

Dachsous, and Fat, upstream of FZ for correct polarity.

During pupal development, order emerges in the retinal epithelium as specific contacts are made between retinal cells. Most of the remaining cell types, including the bristles and the pigment cells, are recruited during pupal stages in a process involving the N-receptor. Cell fate determination depends on each cell's position and contacts. For example, a cell that contacts the anterior or the posterior cone cell becomes a primary pigment cell, whereas a cell that contacts primaries from two distinct ommatidia becomes a secondary pigment cell. A combination of these kinds of cell–cell interactions together with two waves of programmed cell death transforms a nonpatterned epithelium into a

precise array of functional ommatidial units.

Recent data suggest that photoreceptors develop in a two-step process and that each step requires discrete genetic regulation. In the first step, during larval stages, the cells adopt a particular neuronal fate. During the second step, in pupal stages, these neurons execute their differentiation program and acquire final mature properties including *rhodopsin* gene expression. Once the cone cells have closed above the R-cells, the apical surfaces of the photoreceptors involute into the retinal epithelium to form the adult photosensitive rhabdomeres. During subsequent rhabdomere morphogenesis, the prominent adherens junctions between the R-cells are maintained and drive the longitudinal extension of the apical surfaces down to the retinal floor. Recent work has shown that *Drosophila* CRB is essential for rhabdomere elongation and stalk membrane biogenesis. CRB is a central component of a molecular scaffold (also involving β_H-spectrin, moesin, and FERM, a protein 4.1 superfamily member) that controls adherens junction assembly as described in Sect. 1.3 above. Other molecules associated with adherens junctions have also been implicated in rhabdomere elongation. These include Eyes Closed (EYC), the fly homolog of p47, involved in membrane fusion, and the Canoe protein, which is known to bind F-actin. In *eyc* mutants, β-catenin and E-cadherin fail to concentrate into the adherens junctions during pupal stages and this results in fragmented rhabdomeres with inappropriate contacts in the adult. The Canoe gene product directs straight elongation of the rhabdomere, since mutants possess twisted and fused rhabdomeres.

In general, cell–cell and cell–ECM contacts that are established early in eye development persist into adulthood. Rhabdomeres become aligned via cell–cell and cell–ECM adhesions to the retinal floor at the cone cell plate. It has been shown that the integrins play an important role in the development of the three-dimensional structure of the mature retina. Integrin mutants show several eye phenotypes that originate in the structural failure of the cone cell plate. The integrity of the retinal epithelium is intimately linked to its cellular architecture since many of the components necessary for its development and function – such as the integrins, CRB, HNT, and the photopigment, rhodopsin – are also necessary to prevent photoreceptor degeneration. For this reason, the *Drosophila* eye epithelium provides an excellent model for a genetic dissection of the causes underlying progressive human neurodegenerative diseases.

4 Concluding Remarks

The combination of genetic and molecular analyses in model organisms such as *Drosophila*, with biochemical and cell biological analyses on vertebrate cells in culture, has led to a significant understanding of both the structure of epithelia and the mechanisms by which simple, undifferentiated epithelia are converted into complex, differentiated tissues and organs. Since most of the components of epithelia are evolutionarily conserved, results obtained in one organism or cell type have generalized to others. Three areas of research are likely to predominate and synergize in the future. First, novel methods of cell culture, particularly in three dimensions, will lead to increasingly "*in vivo*–like" models of cell behavior, thus

benefiting cell biological and biochemical strategies. Second, the ability to image epithelial shape changes in living tissues or organisms at very high spatial and temporal resolution, and using specific molecular markers, will lead to increased understanding of dynamic changes during epithelial morphogenesis *in vivo*. Finally, the availability of complete genome sequences, together with mutational and phenotypic analysis of evolutionarily conserved components in invertebrate models (e.g. *Drosophila, C. elegans*) as well as in vertebrates (e.g. zebra fish, mouse), will lead to a comprehensive understanding of the structural and regulatory mechanisms of epithelial morphogenesis during animal development.

Keywords

Ca^{2+} Sensor
Protein that detects changes in intracellular Ca^{2+} concentration and controls regulated exocytosis.

Constitutive Exocytosis
Exocytosis involving fusion of new secretory vesicles with the plasma membrane immediately after their synthesis.

Fusion Pore
Aqueous connection between the cell exterior and the inside of a secretory vesicle formed when membrane fusion occurs between the vesicle and plasma membranes.

Regulated Exocytosis
A form of exocytosis in which secretory vesicles are stored within the cells until the appropriate stimulus is generated to trigger their fusion with the plasma membrane.

Secretory Vesicle
Membrane-bounded vesicle containing secretory products or newly synthesized plasma membrane components.

SNARE Proteins
Proteins of the family of α-SNAP receptors that assemble to form a SNARE complex and function in vesicle docking and/or fusion.

Synapse
Junction between the axonal ending of a neuron and another neuron or target cell.

Synaptic Vesicle
Specialized neurotransmitter containing vesicle found in a nerve terminal.

Exocytosis is the process by which secretory vesicles fuse with the plasma membrane of cells to allow release of their contents and insertion of new membrane components. It is a mechanism that is essential for cell growth but also underlies the release of many different extracellularly-acting substances. All cells possess a pathway for constitutive exocytosis and many cell types also possess a pathway for regulated exocytosis that occurs only in response to an intracellular signal such as a rise in cytosolic calcium concentration. Regulated exocytosis is involved in the release of hormones and neurotransmitters and even in events involved in the fusion of the sperm and the egg. In all cases a common conserved machinery is resposible for membrane fusion during exocytosis.

1 Constitutive and Regulated Exocytosis

Exocytosis, the fusion of secretory vesicles with the plasma membrane, occurs in virtually all cells. This is required for the insertion of new plasma membrane lipids and integral membrane proteins such as receptors and ion channels. In addition, exocytosis is the major mechanism by which extracellular proteins are secreted from cells, important examples being antibodies and serum albumin. Such proteins are synthesized on the rough endoplasmic reticulum and delivered to the plasma membrane via the secretory pathway. This comprises a series of sequential membrane trafficking steps, each mediated by the selective targeting and fusion of membrane-bound carriers with appropriate organelle membranes (Fig. 1). As with membrane fusion events earlier in the secretory pathway, exocytosis can follow vesicle formation, without obvious delay or regulation. This ubiquitous process is known as *constitutive exocytosis*. In many cell types, however, a second pathway also exists in which exocytosis is tightly regulated to allow for the controlled release of vesicle contents, or triggered insertion of new membrane components, from preformed secretory vesicles. This process, known as *regulated exocytosis*, occurs only in response to a physiological signal, which in many cell types is a rise in cytosolic Ca^{2+} concentration. Various proteins are secreted by cells via regulated exocytosis, for example, digestive enzymes from exocrine cells and proteinaceous hormones from endocrine cells. In addition, small molecules can be secreted by regulated exocytosis; indeed, this is the mechanism by which neurotransmitters are released at the synapse (Fig. 2). Regulated exocytosis has other fundamental roles such as in the acrosome reaction in the sperm, which is essential for fertilization. The exocytosis of cortical granules in the egg forms the fertilization envelope and prevents further sperm fusion with the egg. The pathway for regulated exocytosis has been extensively studied in many different cell types from various organisms. For constitutive exocytosis, however, the bulk of current knowledge stems from the genetic analysis of this process in the yeast *Saccharomyces cerevisiae*.

Over the past 10 years or so, the use of biochemical, molecular biological, and genetic approaches has identified many of the proteins involved in constitutive exocytosis and in neurotransmission and other forms of regulated exocytosis. The interactions between these proteins and their relationship to membrane fusion have been studied in detail, although the full details of the exocytotic process still remain to be resolved. Similar molecular events appear to underlie all forms of exocytosis and use conserved components of a core vesicle docking/fusion machinery with specialized additions for Ca^{2+}-dependent regulation. We will describe current views on the mechanistic aspects of exocytosis and its triggering and regulation.

2 Stages in the Exocytotic Pathway

For the determination of the distinct stages of exocytosis, Ca^{2+}-regulated exocytosis has been studied in most detail as this most readily lends itself to analysis of the sequential steps involved. It has been dissected into a number of stages (Fig. 2). Regulated exocytosis involves fusion with the plasma membrane of a premade pool

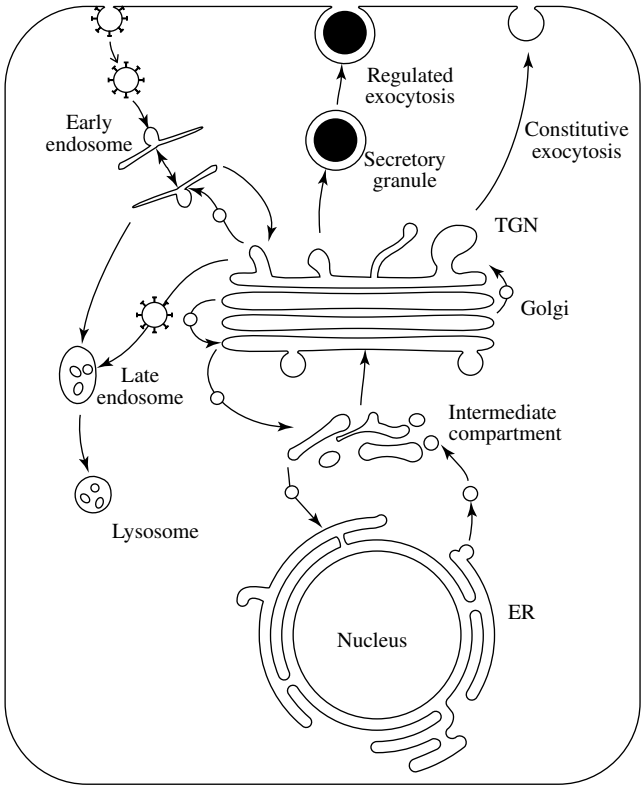

Fig. 1 Schematic representation of membrane trafficking pathways within mammalian cells. Proteins destined for the cell surface are inserted into the ER lumen and then transported forwards by vesicular traffic to the Golgi complex via the intermediate compartment. After sorting in the trans-Golgi network (TGN), proteins enter the secretory vesicle, which can then be directly transported to the cell surface for constitutive exocytosis. Alternatively, proteins are sorted into vesicles or secretory granules and stored until a Ca^{2+} signal triggers regulated exocytosis.

of vesicles. The pool of secretory vesicles may be fully releasable (as in mast cells, for example) but in many cell types (such as neuroendocrine, endocrine, and exocrine cells), a large reserve pool exists and only a small portion of the vesicles is initially releasable. In many cells, a so-called *ready-releasable* pool can undergo exocytosis within tens of milliseconds. These pools have been defined and studied through the use of permeabilized cell assays of exocytosis, single-cell electrophysiological approaches using patch-clamp capacitance measurement of cell surface area, amperometric measurement of the release of single vesicle contents, or by imaging exocytosis through the use of evanescent wave microscopy. The majority of work on synaptic vesicle exocytosis has relied on overall measurement of synaptic transmission based on a simultaneous pre- and postsynaptic recording. Alternatively,

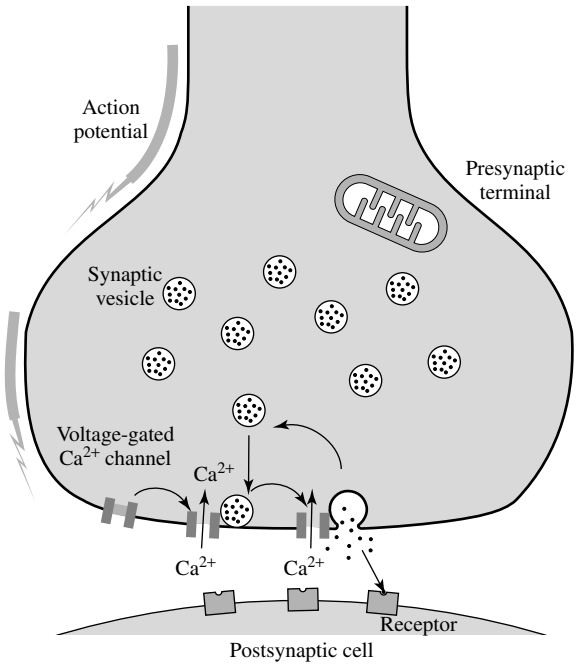

Fig. 2 Neurotransmitter release by exocytosis at the synapse. Voltage-gated Ca^{2+} channels are opened as an action potential reaches the presynaptic nerve terminal leading to Ca^{2+} entry. Synaptic vesicles docked in close proximity to the Ca^{2+} channels then undergo exocytosis within a submillisecond time course to release the stored neurotransmitter.

the synaptic vesicle cycle within synaptic terminals has been studied using uptake and release of the lipophilic FM dyes that report on plasma membrane area and changes following exocytosis and membrane retrieval.

The sequential stages within the exocytotic pathway have been shown to involve ATP-dependent priming steps, movement of vesicles to the vicinity of the plasma membrane, tethering, and then docking at release sites on the plasma membrane, conversion to a fully releasable state, triggered membrane fusion, release of vesicle contents, and finally, retrieval of the vesicle membrane (Fig. 3). In the case of Ca^{2+}-triggered exocytosis, Ca^{2+} may stimulate multiple early stages as well as fusion itself.

2.1 Priming Before Membrane Fusion

The term *priming* was used to describe an ATP-dependent process, demonstrated in permeabilized adrenal chromaffin cells that preceded Ca^{2+}-triggered fusion and increased the extent of exocytosis due to a Ca^{2+} trigger. Priming and membrane fusion were subsequently shown to be stimulated by distinct cytosolic proteins. ATP-dependent priming encompasses multiple events including reorganization of the actin cytoskeleton to allow recruitment

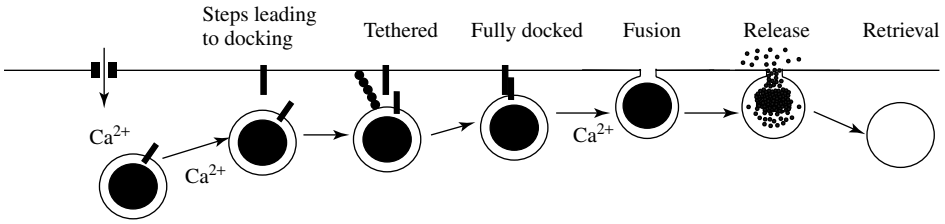

Fig. 3 Stages in the exocytotic pathway. Secretory vesicles are recruited to the plasma membrane where they undergo sequential tethering and then docking so that they become ready for exocytosis. Increased Ca^{2+} concentration can trigger this vesicle recruitment and also fusion of docked vesicles. After exocytosis and release of vesicle contents, vesicles are retrieved back into the cell.

of vesicles to the plasma membrane and modification of the so-called SNARE proteins by α-SNAP and the ATPase NSF. In addition, ATP is also required in a housekeeping role to maintain the levels of polyphosphoinositides required for continued exocytosis. It is well established that membrane fusion itself does not require ATP hydrolysis. The term priming has also been applied to an ill-defined step in synaptic vesicle maturation that may not be ATP-dependent. Within synapses, a pool of synaptic vesicles are described as *docked* as they seem to be very close to the presynaptic plasma membrane by electron microscopical examination. Only a small proportion (around 1–10%) of these vesicles are able to undergo exocytosis in response to Ca^{2+} elevation following a single action potential. This pool of docked vesicles can, however, be completely released through an unknown mechanism, by treatment with hypertonic sucrose. It has been suggested that the so-called *docked* vesicles have to undergo a maturation process to become releasable. This maturation step is not understood in molecular terms but is likely to involve the assembly of the fusion machinery and appears to involve the protein Munc-13.

2.2 Fusion Pores

It has been established through biophysical measurements, that membrane fusion proceeds through the formation of a fusion pore that can open transiently. Patch-clamp measurements of plasma membrane capacitance in mast cells were the first to allow the detection of changes in cell surface area due to single granule fusion events and also demonstrated a phenomenon known as *capacitance flicker*, which suggested that reversible fusion events were occurring. In these cells, Ca^{2+} is not the trigger for exocytosis, which instead can be activated by introduction of nonhydrolyzable GTP analogs. Later, electrophysiological measurements characterized the transient fusion events in mast cells and determined the current flow through the initial fusion pore. The fusion pore can subsequently reclose or alternatively lead to a phase of fusion pore expansion and thereby full exocytosis. The rate of fusion pore expansion was found to be a regulated phenomenon and was increased by elevating intracellular Ca^{2+} concentration in rat mast cells or by activating protein kinase C in eosinophils. The concept of the fusion pore has been validated using carbon-fiber amperometry,

which detected low levels of release of contents from mast cell granules during the initial phase after fusion (during capacitance flickering) and before the postulated fusion pore expansion had occurred.

2.3 Full Fusion Versus Kiss-and-run Exocytosis

Classical electron microscopical studies by Heuser and Reese established a pathway in which synaptic vesicles fused with the presynaptic membrane, moved away from the site of fusion, and were then recycled into the nerve terminal by clathrin-mediated endocytosis. An alternative pathway, later termed *kiss-and-run* fusion, was originally suggested for synaptic vesicle exocytosis and may be related to fusion pore formation and its reversibility. It was postulated that neurotransmitter release from a synaptic vesicle could occur very rapidly without the need for full fusion and flattening of the vesicle membrane into the plasma membrane, but instead by a reversible process that would rapidly retrieve the vesicle membrane for reuse after a transient fusion event. It has been predicted that the contents of a synaptic vesicle could be released on a submillisecond timescale through the type of fusion pore detected in mast cells and described subsequently in other secretory cell types including chromaffin cells, eosinophils, and neutrophils. It has become possible to resolve individual fusion events due to synaptic vesicle exocytosis in a nerve terminal by averaging many thousands of single vesicle fusion events. The data obtained showed that at low stimulus levels, exo/endocytosis was completed on a very short timescale with retrieval having an average time constant of 56 ms consistent with the existence of kiss-and-run exocytosis occurring under these conditions. The significance of kiss-and-run exocytosis for the regulation of neurotransmitter release is a controversial issue. Catecholamine release by kiss-and-run has been directly shown to occur in chromaffin cells using combined capacitance and amperometric recording and based on the trapping of extracellular markers in vesicles after exocytosis.

There is accumulating evidence to suggest that fusion pore closure may be a regulated process that would allow exocytosis to be switched from full fusion to a predominance of kiss-and-run fusion. While kiss-and-run fusion is likely to be sufficient for complete emptying of the synaptic vesicle, large secretory granules may be only partially emptied through a transient fusion process allowing regulation of the amount of release per fusion event. A variety of conditions were found to modify the amount released per granule from chromaffin cells and result in changes in the kinetics of single secretory events consistent with alterations in fusion pore dynamics. These changes could be a consequence of opening and rapid reclosure of a fusion pore, or more likely, reclosure after a period of fusion pore expansion to allow release of secretory vesicle contents. These effects have been seen after phobol ester treatment to activate protein kinase C, modification of intracellular Ca^{2+} levels, nitric oxide application, or following elevation of cAMP levels. Effects on exocytosis kinetics have also been observed in cells overexpressing cysteine string protein (Csp), synaptotagmin, a Munc18 mutant (R39C), a SNAP-25 mutant, or after introduction of anti-CAPS antibodies. In addition, changes in release kinetics, consistent with premature closure of the expanded fusion pore, have

been seen in cells overexpressing complexin, a protein that interacts only with the assembled SNARE complex. A mutation of a residue in complexin that is involved in this interaction prevented the effects on release kinetics. Further work will be needed to explain in detail how fusion pore dynamics are controlled during membrane fusion. A major mechanistic issue for fusion pore reversibility, and thereby, kiss-and-run exocytosis is how fusion pore closure occurs. There are two extreme possibilities. In the first model, the exocytotic machinery that produces fusion acts in a fully reversible fashion. In the second model, the fission machinery responsible for pinching off clathrin-coated endocytotic vesicles on the basis of the action of mechanoenzyme dynamin would be capable of functioning on a millisecond timescale to pinch off fused vesicles. It is also possible that both mechanisms could be operative.

3
The Protein Machinery for Exocytosis

A combination of experimental approaches has resulted in the identification of the protein machinery for exocytosis. From a convergence of biochemical assays and yeast genetics, it became apparent that exocytosis involves a core machinery that functions in both constitutive and regulated exocytosis and that this is highly conserved throughout evolution. The first protein identified using a biochemical approach was *N*-ethylmaleimide-sensitive fusion protein (NSF), which was purified on the basis of its ability to reconstitute intra-Golgi transport after blockade by *N*-ethylmaleimide (NEM). Sequencing revealed that NSF is a homolog of the yeast protein Sec18, which was already known to be essential for membrane traffic. NSF was subsequently found to be involved in regulated exocytosis. Knowledge of the mechanisms involved in exocytosis were advanced by the revelation that NSF and its cofactor, α-soluble NSF attachment protein (α-SNAP), interact with brain membranes via a SNAP receptor (SNARE) complex shown to comprise VAMP/synaptobrevin, syntaxin1, and SNAP-25 with homologs of these proteins being required for secretion in yeast. Genetic approaches have shown the essential nature of the homologs of these proteins in constitutive exocytosis in yeast. The synaptic SNARE proteins are proteolytic substrates for the clostridial neurotoxins, which are potent inhibitors of neurotransmission, thus suggesting that regulated exocytosis at the synapse occurs by the same basic process as constitutive membrane fusion. The idea of a universal fusion machinery is now generally accepted, although the functions of the individual components of the conserved core machinery and the precise mechanism of membrane fusion are still controversial.

3.1
SNARE Proteins and Membrane Fusion

The conserved core vesicle docking/fusion machinery consists of the SNARE proteins, which assemble to form the so-called SNARE complex (Fig. 4) between the vesicle and plasma membrane. Although originally defined biochemically as SNAP receptors, most SNAREs have been identified by possession of a characteristic sequence known as the SNARE motif. Searching for similar motifs in the human genome revealed 35 SNAREs, as compared to 22 in the yeast genome. Despite the large number of SNARE proteins, the synaptic SNARE complex remains the

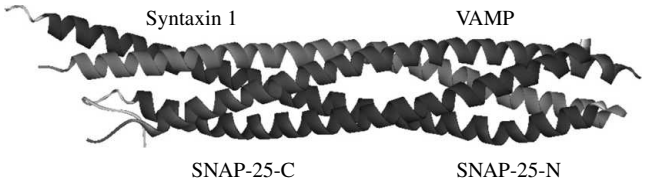

Fig. 4 The structure of the SNARE complex. The structure of the neuronal SNARE complex consisting of the cytoplasmic domains of syntaxin 1A, VAMP2, and SNAP-25 was determined by X-ray crystallography.

most intensively studied and most current ideas of SNARE function are based on this particular complex. It comprises three proteins: the integral membrane proteins, VAMP/synaptobrevin and syntaxin 1, and the membrane associated protein, SNAP-25. VAMP is a synaptic vesicle protein, whereas syntaxin and SNAP-25 are most enriched in the presynaptic plasma membrane. These localizations led to the classification of SNAREs as vesicle- (v-) or target- (t-)SNAREs, and the SNARE hypothesis suggested that the fidelity of vesicle docking and fusion is determined by the specificity of v-SNARE : t-SNARE interactions. More recently, a rival classification system has been proposed based on whether a conserved glutamine (Q) or arginine (R) is present in the SNARE motif in the so-called *zero layer* observed in the structure of the neuronal SNARE complex. The Q and R residues themselves, however, are not essential for membrane fusion but instead for the later disassembly of the SNARE complex by NSF and SNAPs.

The idea that SNARE complexes are essential for membrane fusion in living cells is well supported by genetic studies in yeast and higher organisms. Genetic ablation of synaptic SNAREs in *Drosophila melanogaster*, *Caenorhabditis elegans*, and *Mus musculus* abolishes evoked neurotransmission. It is interesting to note, however, that the effect of inactivating syntaxins tends to be more dramatic than when other SNAREs are blocked. The use of clostridial neurotoxins has also provided important evidence for an essential role of SNAREs in exocytosis in various cell types. The key discovery in this regard was that tetanus and botulinum-B neurotoxin are metalloendoproteases that block neurotransmission presynaptically by selectively cleaving VAMP. It was then established that the remaining six botulinum neurotoxins cleaved either VAMP, syntaxin 1, or SNAP-25. Clostridial neurotoxins have been applied to many permeabilized secretory cells. Not all forms of exocytosis are blocked by clostridial neurotoxins but the most likely explanation for this is that exocytosis in such cells proceeds via toxin-resistant SNARE isoforms.

Several lines of evidence suggest that SNAREs participate in and may directly drive membrane fusion. First, tetanus toxin application results in the accumulation of docked vesicles at the synapse, suggesting that SNAREs function after morphological vesicle docking. Second, formation of the SNARE complex is energetically favorable (assembled SNARE complexes have extremely high thermal stability and require NSF and α-SNAP for disassembly). Third, the structure of the synaptic SNARE complex is such that formation of its coiled-coil bundle (Fig. 4)

would bring the transmembrane anchors of VAMP and syntaxin (and hence the vesicle and plasma membrane) into close apposition. Fourth, membrane fusion between artificial liposomes has been reconstituted using only recombinant SNAREs. These data have been taken as suggesting that the SNAREs form the core fusion machinery. This model, although popular, is not without its critics, however, as SNARE-mediated fusion is many orders of time slower than exocytosis. In addition, one controversial theory, based on studies of yeast vacuole fusion, contends that SNARE complex formation is an early event that acts as a signal to initiate an entirely different fusion mechanism that is ultimately mediated by vacuolar ATPase proteolipids. Clearly, further work is required for a full understanding of the events that lead to membrane fusion.

3.2 SNARE Regulators

3.2.1 NSF and α-SNAP

NSF and α-SNAP are soluble proteins that act to disassemble SNARE complexes. Due to the high stability of the SNARE complex, disassembly requires significant energy input in the form of ATP hydrolysis. This is provided by the ATPase NSF, and SNAP stimulation of the ATPase activity of NSF is essential for SNARE complex disassembly. It is thought that the conformational changes in NSF induced by ATP hydrolysis are transduced through α-SNAP to unwind the four helices of the SNARE complex.

The first evidence for a requirement of NSF and SNAPs in membrane fusion *in vivo* came from the yeast Sec17 and Sec18 mutants, which encode α-SNAP and NSF respectively, and are essential for all membrane trafficking steps. A role for NSF in regulated exocytosis *in vivo* was revealed by studies of the *comatose* (NSF) mutants in *D. melanogaster*. These mutants show a temperature-sensitive block in presynaptic neurotransmission. The mutant organisms accumulate SNARE complexes at the restrictive temperature, confirming that NSF is required to disassemble SNAREs in living cells. Questions remained, however, over the precise point in the membrane fusion process at which NSF and α-SNAP act. The use of stage-specific exocytosis assays in permeabilized secretory cells and high-resolution electrophysiological approaches have established that α-SNAP/NSF act in an early ATP-dependent priming reaction that precedes the later Ca^{2+}-dependent fusion step. Furthermore, this priming reaction is likely to be the disassembly of SNARE complexes, since mutant α-SNAPs unable to stimulate NSF ATPase activity and consequent SNARE disassembly cannot support exocytosis. It seems that α-SNAP/NSF act as molecular chaperones, continually disassembling SNARE complexes in order to release SNARE proteins to engage and function in further membrane fusion events.

3.2.2 Sec1 Proteins

Much attention has been focused on NSF, SNAPs, and SNAREs, but these are not the only evolutionarily conserved proteins required for intracellular membrane traffic. The first yeast secretory mutant to be identified harbored a mutation in Sec1. Genetic studies have established a general requirement for Sec1-related proteins in vesicle fusion in a wide variety of organisms. Sec1 family members have been shown to interact with syntaxin homologs, suggesting that the conserved function of Sec1 proteins in membrane fusion may be mediated via syntaxins. Indeed, the inhibition of neurotransmitter release in *Drosophila*

caused by overexpression of ROP is relieved by co-overexpression of syntaxin. Neuronal Sec1 (also known as Munc18) binds to syntaxin1a with high affinity *in vitro* to form a complex that precludes syntaxin binding to synaptic SNAREs. These observations have led to the suggestion that Sec1 proteins act as syntaxin chaperones, preventing SNARE complex assembly until signaled to release syntaxin. Although the precise nature of this signal is unknown, various observations suggest that it is linked to the completion of Rab-dependent vesicle tethering.

The proposed role of Sec1 proteins as negative regulators of syntaxin function is too simplistic as loss of Sec1 family members results in a complete block in membrane traffic, indicating an essential positive role. Studies of nSec1/Munc18 in PC12 cells suggest that, rather than merely preventing syntaxin entry into the core complex, the syntaxin–Sec1 interaction is an essential intermediate that enables activation of syntaxin for efficient incorporation into the SNARE complex. This notion is consistent with recent studies in chromaffin cells on the effects of a mutant form of nSec1/Munc18 (R39C) with a reduced affinity for syntaxin. Here, it was found that the mutant resulted in an increased rate of fusion pore expansion, which could result from the increased release of activated syntaxin into the fusion machinery. In contrast to neuronal Sec1, yeast Sec1will not bind efficiently to its cognate syntaxin (Sso1/2) in isolation, but only when it is assembled into a SNARE complex. This finding suggests that Sec1 functions during the membrane fusion process, acting at or after SNARE assembly consistent with a second effect of the Munc18 mutant to cause rapid closure of the fusion pore. In contrast to these models, studies of chromaffin cells from Munc18-1 knockout mice have revealed a major defect in granule docking, suggesting a much earlier role for this protein. Clearly, Sec1 proteins have essential and possibly multiple functions in physiological membrane fusion.

3.3 Rab GTPases and Their Effectors

Rab proteins comprise a large family of small GTPases. Individual Rab proteins are localized to distinct organelles, suggesting that each regulates a particular membrane traffic step. Rabs are thought to act as molecular switches determining how long vesicles remain competent for docking/fusion, before GTP hydrolysis. The initial findings implicating these GTPases in membrane traffic came from the identification of the Sec4 mutation which blocks constitutive exocytosis in yeast. The general consensus is that Rabs are major determinants of the specificity of membrane transport, and achieve this by selective interactions with distinct effector proteins. The best-characterized Rab effectors are involved in the initial tethering of vesicles to target membranes (Fig. 5). These include the exocyst complex (Sec4 effector in exocytosis in yeast) and EEA1 (Rab5 effector in endocytosis). Another class of Rab effectors is the motor proteins that act to control organelle movement within cells. For example, Rab5 controls movement of endosomes on microtubules and Rab6 binds to the kinesin-like protein, rabkinesin-6. In addition to microtubule-based motors, Rabs have also been implicated in actin-based motility by virtue of functional interactions with class V myosins. Finally, genetic (and in some cases, physical) interactions between various Sec1 homologs and Rabs suggest that

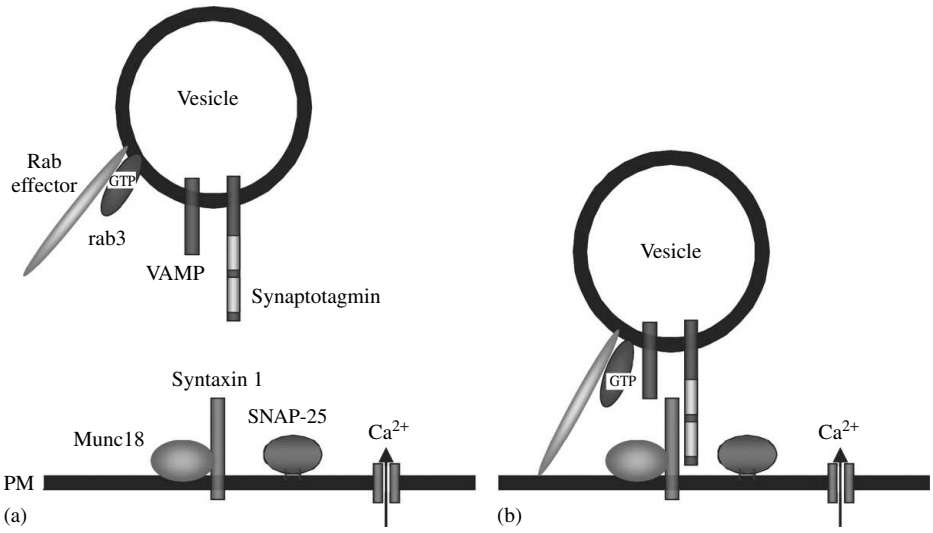

Fig. 5 Localization of proteins involved in exocytosis and role of Rab3 in tethering. The diagram shows the distribution of synaptic proteins on synaptic vesicles and the presynaptic membrane. When Rab3 becomes GTP-loaded (a), it recruits effectors that allow tethering of vesicles, (b) prior to engagement of the SNARE proteins.

the Sec1 family may represent a third distinct class of Rab effectors. However, a variety of other proteins that do not clearly segregate into these classes have also been proposed as Rab effectors, emphasizing the potential complexity of Rab function(s) in the cell.

Rab3 exists as four isoforms A–D in mammals and is the major Rab implicated in exocytosis in neurons and neuroendocrine cells. Rab3A is not an essential protein in mammals but may regulate neurosecretion by limiting the recruitment of synaptic vesicles into the releasable pool at the plasma membrane for subsequent fusion events. Rab3 mutants in *C. elegans* are also viable but have less synaptic vesicles close to the presynaptic membrane. Surprisingly, overexpression of active forms of Rab3A or other Rab3 isoforms has been found to inhibit exocytosis in various cell types. Several Rab3A effector proteins including RIM and Rabphilin 3A are involved in secretory vesicle exocytosis. Analysis of specific mutations that disrupt interaction of Rab3 with these effectors has excluded them, however, as the inhibitory effectors of Rab3. The inhibitory effects of Rab3 may instead be exerted via the effector Noc2, a protein expressed predominantly, if not exclusively, in neuroendocrine cells. Other studies have suggested that certain Rab3 isoforms may, in contrast, exert positive effects on exocytosis in some cell types. It is possible that Rab3 has multiple roles in exocytosis. Despite the suggestions that different Rab3 isoforms have distinct functions, a direct test of this possibility shows that the four Rab3A–D isoforms all had the same inhibitory effect after overexpression in PC12, chromaffin, and insulin-secreting cell lines. In addition, more recent work has established an important role for Rab27 in exocytosis in melanocytes and in cytotoxic T

lymphocytes and also in dense-core granule exocytosis in endocrine cells.

3.4 A Model for the Events Leading to Membrane Fusion

Figure 6 shows a model that has developed from the studies described above on the interactions of the SNARE proteins and their regulatory proteins. In this scheme, syntaxin is held in its closed conformation by Munc18. In some ill-defined way, possibly due to the action of a Rab/Rab effector, Munc18 is dissociated from syntaxin. Syntaxin then adopts its open confirmation, although Munc18 may remain present due to alternative interactions with the N-terminus of syntaxin. The SNARE helix of syntaxin, which is now exposed, acts as a nucleation site for interaction with the VAMP SNARE domain and the two helices of SNAP-25. Formation of the full complex then proceeds down its energy gradient, potentially releasing sufficient energy to overcome the hydration barrier and initiate bilayer fusion. Munc18 appears to be able to exert effects on the kinetics of the fusion process. After fusion, the SNARE complex is disassembled by α-SNAP and NSF, and Munc18 reforms its tight complex with the closed form of syntaxin.

4 Calcium Signals and Exocytosis

A number of different intracellular signals are involved in triggering regulated exocytosis. The most widespread and most

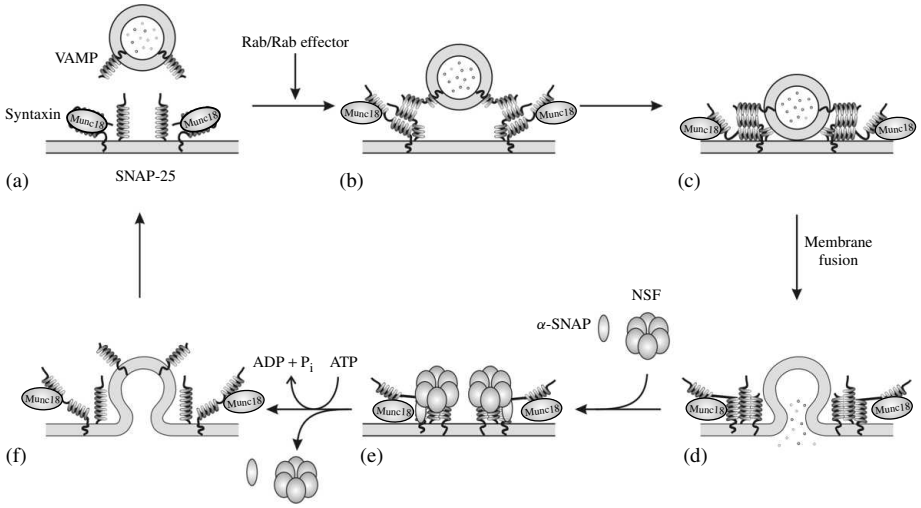

Fig. 6 Model of the protein–protein interactions to lead to and follow exocytosis. (a) Syntaxin is initially held in a closed conformation by Munc18, which prevents SNARE complex assembly. (b) Tethering due to the action of Rab/Rab effector leads to release of syntaxin by Munc18 into its open conformation and SNARE complex assembly begins. (c) Full assembly of the SNARE complex pulls the vesicle into proximity with the plasma membrane and (d) leads to membrane fusion. (e) After fusion, SNARE complexes bind α-SNAP and NSF and (f) these are disassembled following ATP hydrolysis by NSF. Munc18 can then interact with syntaxin to reform its closed conformation. Munc18 exerts additional effects during membrane fusion through as-yet uncharacterized interactions.

intensively studied is cytosolic Ca^{2+} concentration. In many cell types, regulated exocytosis is triggered by an elevation of cytosolic Ca^{2+} concentration from a resting level of 100 nM to micromolar concentrations due to Ca^{2+} entry at the plasma membrane or mobilization from intracellular stores. The limited diffusion of Ca^{2+} due to high levels of Ca^{2+} buffering within cells limits the distance over which Ca^{2+} can diffuse and exert its effects. Spatial distribution may result in only particular types of Ca^{2+} channels being associated with exocytosis and this may be enhanced by physical association of vesicles with Ca^{2+} channel proteins, as is believed to occur for P/Q- and N-type channels in synapses. The increased importance of Ca^{2+} stores in pancreatic exocrine cells and pituitary gonadotrophs appears to be determined by the spatial localization of ER Ca^{2+} stores in these cell types.

4.1 Calcium-dependency of Regulated Exocytosis

Considerable effort has been expended in the determination of the Ca^{2+} sensitivity of the exocytotic machinery in a wide range of cell types. Two major technical approaches have been used. Firstly, cell population measurements of granule release following cell permeabilization with direct addition of Ca^{2+}, and secondly, single-cell patch-clamp capacitance recording to follow the kinetics of exocytosis. Katz and Miledi established the importance of Ca^{2+} by showing a requirement for external Ca^{2+} for the release process at the neuromuscular junction. This was subsequently extended by Bill Douglas to chromaffin cells and posterior pituitary neurosecretory terminals. Assessment of the Ca^{2+}-dependency of exocytosis required, however, the means to control the internal Ca^{2+} concentration. This was first achieved by the use of electropermeabilization of sea urchin eggs and adrenal chromaffin cells and application of buffered Ca^{2+} solutions to the leaky cells. This revealed that granule exocytosis in these cells was half-maximally activated at 1 µM free Ca^{2+}. The similar Ca^{2+}-dependency of fusion in these two cell types suggested the possible existence of a common Ca^{2+} sensor mechanism in exocytosis. In the majority of cases, the use of permeabilized cells has shown a Ca^{2+} requirement for triggering of exocytosis in the low micromolar range. It later became apparent, however, that multiple Ca^{2+}-dependent steps exist in the exocytotic pathway.

A value for the Ca^{2+}-dependency of the final fusion step in regulated exocytosis in endocrine and other secretory cells was subsequently determined by patch-clamp measurement of plasma membrane capacitance. Membrane capacitance is directly proportional to the area of the lipid bilayer and so this technique allows quantitative assay of membrane insertion (exocytosis) or membrane removal (endocytosis) from the cell surface. In early studies, exocytosis was triggered by depolarization to open voltage-gated Ca^{2+} channels or by infusion of Ca^{2+}-buffers from the recording micropipette by intracellular dialysis. Accurate determination of the Ca^{2+} requirement of the final fusion step was achieved by using flash photolysis to break downcaged Ca^{2+} compounds and to give a homogenous elevation of free Ca^{2+} coupled with capacitance recording. This approach allowed an assessment of the relationship between free Ca^{2+} concentration and the initial rate of exocytosis from the ready-releasable pool. Such experiments, carried out in a range of endocrine

cell types, demonstrated rapid exocytosis with a Ca^{2+}-dependency in the 2 to 30 μM range.

4.2 Calcium-dependency of Synaptic Vesicle Exocytosis

Use of the flash photolysis/capacitance method on a specialized neuron, the retinal bipolar neuron, suggested that synaptic vesicle exocytosis involved a distinct low-affinity Ca^{2+} sensor. In this giant synapse, exocytosis was not detected until the Ca^{2+} concentration was $>10-20$ μM and was half-maximal at 190 μM free Ca^{2+}, a 10-fold higher Ca^{2+} concentration than for endocrine cell exocytosis. More recently, measurement of neurotransmission at a central mammalian synapse (the calyx of Held) has determined a Ca^{2+}-dependency in the low micromolar range (2–5 μM) comparable to that for endocrine cell exocytosis. These findings were interpreted as suggesting that the earlier value found in retinal bipolar neurons might not reflect the general situation in mammalian CNS synapses. Earlier data in support of a low-affinity receptor for synaptic vesicle exocytosis in the squid giant synapse included the demonstration of microdomains of very high Ca^{2+} during neurotransmitter release. In addition, exocytosis in this synapse was inhibited by the fast Ca^{2+} chelator BAPTA but not by the slower Ca^{2+} chelator EGTA suggesting that the sensing of Ca^{2+} by the fusion machinery must occur close to the Ca^{2+} channels. It is possible that the Held synaptic terminals are unusual in their Ca^{2+} requirements but blockade of transmission by the slow Ca^{2+} chelator EGTA in cortical synapses favors more widespread use of a low-affinity process.

4.3 Spatial Relationship of Channels and Vesicles

A further issue in understanding the relationship between Ca^{2+} and regulated exocytosis is the spatial distribution of secretory vesicles and the source of Ca^{2+}. In addition, much attention has been given to the question of how close fusion occurs to Ca^{2+} channels and the degree of coupling between Ca^{2+} entry and exocytosis. For synaptic vesicles, it is generally agreed that the rapid speed of neurotransmission, which can be as fast as 60 μs in central synapses, must mean that the vesicles that undergo fusion sense Ca^{2+} that has diffused no further than a few nanometers from the mouth of the open Ca^{2+} channel. This must also be the case if synaptic vesicle exocytosis involves a low-affinity Ca^{2+}-sensor. Molecular interactions that have been demonstrated between proteins of the exocytosis machinery and Ca^{2+} channel subunits suggest that synaptic voltage-gated Ca^{2+} channels involved in neurotransmission are physically part of the exocytotic site. The extent of coupling to Ca^{2+} channels has been examined for endocrine granule exocytosis in adrenal chromaffin cells and it has been suggested that a tight physical coupling between Ca^{2+} channels and secretory granules is unlikely to occur in these cells.

4.4 Calcium and Exocytosis in Nonsecretory Cells

The application of flash photolysis of caged Ca^{2+} compounds and patch-clamp capacitance recording to cultured fibroblastoid cell lines surprisingly showed that a Ca^{2+}-regulated pathway for exocytosis

existed even in these cells. Coupled with the demonstration that muscle myoblasts could take up and release acetylcholine in response to stimulation, this suggests that all cell types might possess a regulated exocytotic pathway. One possibility is that this pathway involves Ca^{2+}-dependent exocytosis of lysosomes as it has been demonstrated that even in nonsecretory cells, conventional lysosomes can be triggered to undergo exocytosis.

5 The Calcium Sensor for Regulated Exocytosis

The major role of Ca^{2+} as the trigger for regulated exocytosis predicts the existence of a conserved protein(s) capable of activating the SNARE-related fusion machinery upon binding Ca^{2+}. Several different candidate proteins have been put forward, but it now seems clear that synaptotagmin is the major Ca^{2+} sensor for regulated exocytosis. Originally discovered over 20 years ago as a synaptic vesicle membrane protein, termed p65, interest in this protein increased dramatically with the demonstration that it was a Ca^{2+}-dependent phospholipid-binding protein. This property of synaptotagmin is due to its two C_2 domains, C_2A and C_2B (Fig. 7), which are homologous to the C_2 domain in protein kinase C. Considerable variation in the Ca^{2+} dependence of phospholipid binding is exhibited by different synaptotagmin isoforms, with the plasma membrane synaptotagmins 3 and 7 displaying much higher Ca^{2+} affinity (EC_{50} of 1–2 μM) than the vesicular synaptotagmins 1 and 2 (EC_{50} of 10–20 μM). In addition, synaptotagmins have been shown to interact with a variety of proteins implicated in exocytosis, including Ca^{2+} channels, syntaxin 1, the SNARE complex, and β-SNAP. Synaptotagmin I can accelerate liposome fusion mediated by SNAREs but in a Ca^{2+}-independent manner. As with phospholipid binding, individual synaptotagmins display marked differences in the Ca^{2+}-dependency of syntaxin binding, with >200 μM Ca^{2+} required for maximal binding by synaptotagmins 1 and 2, in contrast with <10 μM Ca^{2+} for synaptotagmins 3 and 7. Recent work suggests that the key Ca^{2+}-dependent interaction for exocytosis involving synaptotagmin is with phospholipids.

Synaptotagmins may be the ubiquitous exocytotic Ca^{2+} sensors. Evidence to support this view comes from genetic studies in *Drosophila*, *C. elegans*, and mice, where synaptotagmin mutants display impaired synaptic transmission. In addition, mice with a point mutation (R233Q) reducing the affinity of synaptotagmin 1 for Ca^{2+}-dependent phospholipid binding display a decrease in the Ca^{2+} affinity of synaptic vesicle exocytosis. This strongly suggests that synaptotagmin 1 is a major Ca^{2+} sensor for synaptic vesicle exocytosis. A further aspect of synaptotagmin that has emerged is its ability to influence the kinetics of single granule release events in PC12 cells, suggesting that it may function during membrane fusion at the level of the fusion pore. The significance of Ca^{2+} sensing by either the C2A or C2B domains of synaptotagmin has been controversial. As noted above, the knock-in study on the R233Q mutant in mice suggested the importance of the C2A domain for the Ca^{2+} sensitivity of exocytosis. Detailed genetic analyses in *Drosophila* have shown, however, that Ca^{2+}-binding to the C2A domain is dispensable for neurotransmission and survival but that Ca^{2+}-binding to the C2B domain is crucial. Whilst it is clear that synaptotagmin plays a major role

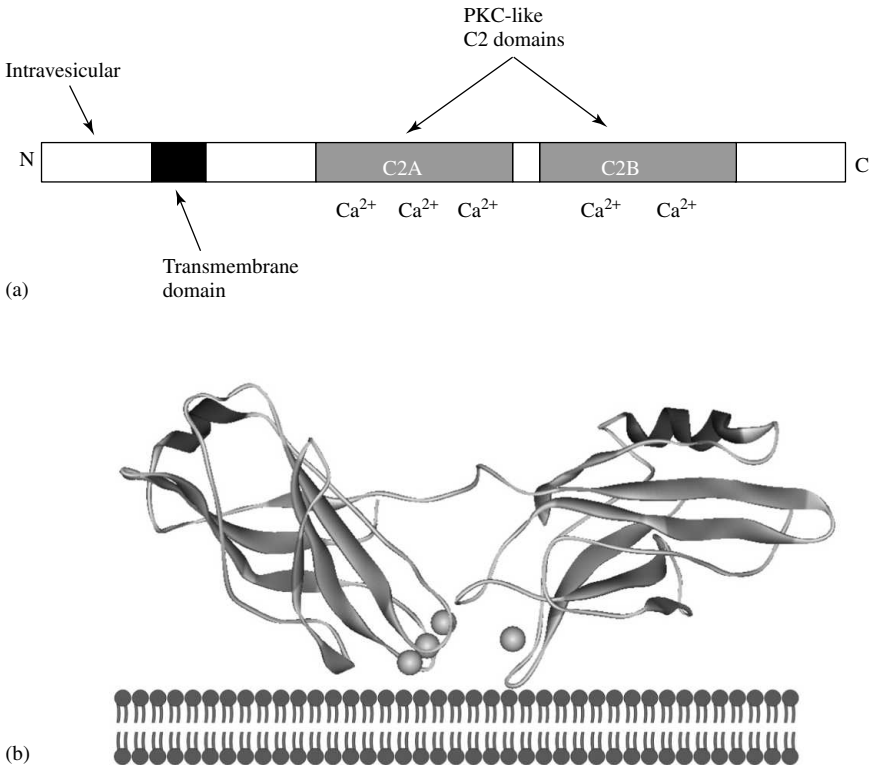

Fig. 7 Structure of synaptotagmins. (a) Domain organization of the synaptotagmins. (b) Structure of the cytoplasmic domain of synaptotagmin III. Synaptotagmin contains two C_2 domains with divalent cation binding sites occupied in the crystal by three (C2A, left) or one (C2B, right) Mg^{2+} ions. The side of the molecule that binds Ca^{2+} or Mg^{2+} also interacts with phospholipids.

in regulated exocytosis, how it contributes and when it acts during the steps leading to membrane fusion are unknown. In some models, synaptotagmin has a negative role in preventing SNARE-mediated fusion until the Ca^{2+} signal appears. In others, synaptotagmin has been proposed to play an active part in membrane fusion. Clearly, much is still to be learnt about this already extensively studied protein.

Other Ca^{2+} sensors may also contribute to the regulation of exocytosis. The C_2 domains present in synaptotagmin are also shared by protein kinase C, rabphilin 3A, Doc2, RIM, and munc13, all of which have been suggested to play a role in exocytosis. Ca^{2+} binding proteins that lack C_2 domains have also been implicated in granule exocytosis. Calmodulin binds Ca^{2+} via its four EF-hand domains and was one of the first proteins suggested to be involved in exocytosis. More recently, Ca^{2+}-calmodulin has been invoked as a universal requirement for the membrane fusion process, based on observations from several constitutive membrane fusion events. However, in some cell types, exocytosis is not blocked by calmodulin antagonists and so a regulatory rather than an essential role for this protein in exocytosis is likely.

6 Conclusions

The study of exocytosis for many years in a wide range of cell types has resulted in extensive characterization of the physiological regulation of secretion. For a long time, it was suspected that the mechanisms underlying regulated exocytosis would be different from cell to cell and, in particular, would be distinct in synapses where exocytosis is very rapid. The last few decades or so have seen an incredible explosion in our knowledge of the many proteins that form the machinery for vesicle docking and fusion in exocytosis and that regulate the process. One of the most striking aspects has been the discovery in the early 1990s that very similar proteins play the same roles in synaptic exocytosis and in constitutive exocytosis in yeast and thus form part of a highly conserved machinery. The expression of SNARE isoforms and their regulators has now been cataloged extensively in many types of secretory cells. It is apparent, therefore, that essentially the same core machinery with identical proteins (or closely related isoforms of them) functions in exocytosis in all cell types that have been examined and that these are universally essential proteins. A similar core machinery also functions in all other intracellular fusion events underlying membrane traffic within the cell. The universality of mechanisms underlying exocytosis has greatly simplified our thinking and resulted in a concentrated analysis of favored model secretory cells. A number of issues remain to be resolved for a full understanding of exocytosis. It is not yet completely clear whether the SNAREs are the proteins that drive membrane fusion or whether other proteins do this job alone or in conjunction with the SNAREs. The behavior of the lipid bilayers during membrane fusion, fusion pore formation, and pore expansion is an area about which little is known. The way in which synaptotagmin controls regulated exocytosis and the extent to which it participates in membrane fusion is unclear. After more than a decade of considerable advances in the study of exocytosis, we are now poised, however, to answer these final questions regarding the exact mechanisms involved in the important biological process of exocytosis.

Keywords

Complementation
The functional replacement of a mutated or deleted endogenous gene in a given organism by a gene introduced and expressed in that organism.

Enhancer Screen
A genetic screen to identify mutants that exhibit a more severely altered phenotype.

Epistasis
A situation in which a mutation in one gene (the epistatic gene) masks the phenotype of a mutation in another gene (the hypostatic gene); epistasis analysis refers to a genetic technique used to determine whether two proteins function in the same pathway, and if so, to order the proteins in the pathway.

High-throughput Screening
Screening of large numbers (100 000 to 1 000 000) of compounds (small molecules, natural products) using a format (biophysical, biochemical or functional assay) and a process (robotics, automation, miniaturization) that allow screening to be completed in a few days.

Lead Optimization
Chemistry devoted to improving the quality of a compound obtained from high-throughput screening, through optimization of the potency, efficacy, specificity, safety, pharmacokinetic and drug metabolism profiles.

Suppressor Screen
A genetic screen to identify mutants that result in reversion of an altered phenotype to a wild-type phenotype.

Synthetic Lethality
A situation in which two mutations (typically in different genes) cause lethality when present in combination, but do not give rise to a lethal phenotype when present individually.

Model organisms provide highly relevant and convenient platforms for characterizing novel protein functions and elucidating complex biological systems, including defining the roles of these proteins and systems in disease processes. This chapter describes various practical uses of model organisms (yeast, fly, worm, fish, and mouse) that contribute to the identification and validation of human therapeutic targets as well as impact on early drug development.

1
Exploiting Model Organisms for Disease Intervention

A major challenge in biomedical and pharmaceutical research is to understand the biological functions of proteins as they relate to human diseases, and to select the most promising targets for therapeutic intervention. A general roadmap of the drug discovery and development process is shown in Fig. 1.

The initial step of target identification is followed by target validation, which involves detailed studies to correlate a protein and its function with disease onset or progression. Once sufficient biological validation is available for a given target, a biophysical, biochemical or biological assay is developed and high-throughput screening is conducted to identify lead compounds (inhibitors, agonists, antagonists). This is followed by successive rounds of medicinal chemistry to optimize the lead compound, with the goal of improving its potency, efficacy, specificity, safety, pharmacokinetic and drug metabolism properties. Optimized compounds are then tested for safety and efficacy in animals and subsequently in human subjects in a series of clinical trials typically involving healthy volunteers (phase I) and patients (phases II and III).

The entire process of drug discovery and development requires an enormous expenditure of time and resources without the guarantee of bringing a drug to market, and only a small percentage of compounds successfully progress through preclinical and clinical testing and make it to the marketplace as new drugs. Hence, in an effort to reduce attrition of compounds during the late and costly phases of drug development, and to increase the overall probability of success, novel approaches are implemented upfront to significantly increase the biological validation of the therapeutic targets. The human genome sequence is actively being mined for new genes that play a central role in the onset or progression of pathophysiologies. The selection of successful therapeutic targets depends largely on the generation and integration of high-quality data from a variety of applied genomic, genetic, and biological technologies. A key element of genomics-based drug discovery today involves comparative and functional genomic studies in model organisms, including yeasts (*Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*), invertebrates (the soil nematode, *Caenorhabditis elegans*, and the fruit fly, *Drosophila melanogaster*), lower vertebrates (zebrafish, *Danio rerio*), and rodents (the mouse, *Mus musculus*, and the rat, *Rattus norvegicus*), with the aim of delineating gene functions in the context of a whole organism

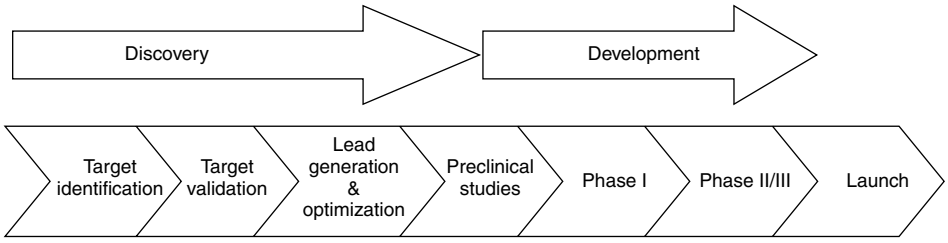

Fig. 1 Schematic representation of the typical drug discovery and development process.

that can be easily, rapidly and inexpensively manipulated. Gene-driven biology in these model organisms has dramatically advanced the understanding and exploitation of human proteins as therapeutic targets, and is contributing to the development of new medicines and new strategies for therapeutic intervention. The most important element for success with these highly diverse model organisms is knowing how to exploit their respective distinct advantages, and asking the right biological questions in the case of each right organism.

2
Model Organism Biology

The completion of the human genome sequence has served as a springboard for studying the functions of novel genes in *in vivo* systems, with special interest in model organisms that afford a high-throughput format and whose biology is as close to human biology as possible. Since the time and resources needed to generate transgenic rodents do not allow high-throughput studies in these organisms, scientists turned to simpler model organisms in which gene inactivation, pathway analysis and compound testing can be more easily performed, and in which results can be more easily interpreted. The data are then translated back to mammalian or, ideally, human systems where the proposed functions and processes can be verified. There are many advantages of working with nonmammalian model systems. The experiments are relatively fast, inexpensive, in some cases amenable to automation, and quite often highly informative, thereby contributing to our overall understanding of protein functions.

2.1
Yeast and Invertebrate Organisms

Many biological pathways relevant to humans are not only conserved, but were actually first uncovered in nonmammalian systems. The Nobel prize-winning work of Lee Hartwell, Paul Nurse, and Timothy Hunt to identify and analyze cell division cycle (CDC) mutants in yeast led to the current understanding of the human cell cycle and DNA repair and, ultimately, to a better understanding of cancer biology. Similarly, much of what we know about the critical players in Alzheimer's (presenilins, amyloid precursor protein (APP) and tau), Parkinson's (parkin) and Huntington's diseases were elucidated in the fly and in the worm.

In fact, a great deal of functional knowledge about mammalian proteins in general has been deduced through comparative bioinformatics and experimentally derived functions of orthologous proteins in yeast, worm, and fly. All of these species offer complete genome sequences with fully annotated core proteomes. Although there is considerable protein sequence conservation in many disease genes and protein classes, the key from a therapeutic perspective is to find disease relevance for members of protein families proven to be tractable (''druggable''), including G-protein coupled receptors (GPCRs), nuclear hormone receptors (NHRs), enzymes, and ion channels. These protein classes are collectively represented in the lower model organisms (Table 1). Much of the difference in the number of genes in each model organism as compared to humans, and therefore the number of orthologous relationships between humans and relatively simple model organisms can be attributed to the fact that the function of a single gene in a model

Tab. 1 Model organism orthologs[a] for major traditional drug target protein classes.

	C. elegans	*D. melanogaster*	*S. cerevisiae*	*S. pombe*
GPCRs	28	38	–	–
NRs	13	12	–	–
Kinases	143	150	48	57
Proteases[b]	110	121	50	59
Channels	54	60	6	6

[a] Strict orthologs were reciprocal-BLAST validated. They were obtained by BLAST analysis of each human target class protein to all proteins in each organism. The top model organism hit was then used for BLAST analysis versus a human protein database. If the top human hit from this second BLAST was the same as the human protein used in the first BLAST analysis, then a strict orthologous relationship was said to exist.
[b] Proteasome subunits were not included in the analysis.
Notes: GPCR: G-protein coupled receptor; NR: Nuclear Hormone Receptor.

organism is often fulfilled by two or three genes in humans, where each human gene has a highly specialized function. An example of this is provided by the *aurora* gene, a key mitotic regulator. In yeast, there is one gene (*IPL*), in *C. elegans* there are two genes (*air-1* and *air-2*), in *Drosophila* there are two genes (*aurora* and *ia1*), and in mammals there are three genes (*Aurora A*, *B*, and *C*).

Comparative genome sequence analyses have revealed that the *Drosophila* proteome (as compared to that of yeast and worm) is more similar to mammalian proteomes. For instance, although the fly has considerably fewer GPCRs than the worm (~160 and ~1100 GPCRs in the fly and worm respectively), the fly has a greater number of orthologous relationships with human GPCRs than the worm. In addition, despite the lesser number of NHRs in the fly compared to the worm, there are the same number of orthologous relationships between human and fly NHRs as there are between human and worm NHRs, and there is greater sequence conservation between fly and human NHRs than between human and worm NHRs. Also, it has been established that 60 to 80% of disease-linked human genes have fly orthologs while only 42 to 50% and ~30% of human disease-linked genes have orthologs in worms and yeast respectively. The high degree of sequence conservation between human and fly genes, the complex nature of the organism, and the availability of thousands of mutants has made *Drosophila* the most widely used invertebrate multicellular organism for genetic studies. However, the inability in maintaining frozen stocks, the difficulty in establishing truly high-throughput assays and the difficulty in treating flies with compounds are making this organism less attractive for focused drug discovery studies.

The soil nematode, *C. elegans*, was not used as a model organism until the mid 1960s when Sydney Brenner recognized its potential as a model system to study animal development. His pioneering work along with that of Robert Horvitz and John Sulston was recognized in 2002 with their receiving the Nobel Prize for Medicine. The success of *C. elegans* as a model

organism can be attributed to its ease of cultivation in the lab. This free-living soil nematode, approximately 1 mm in length, has a rapid life cycle (3 days), feeds on *Escherichia coli*, and can be grown in 96- and 384-well formats. Its transparent body allows one to readily observe physiological defects in live worms. In addition, the use of transgenic worm lines expressing transcriptional or translational fusions to green fluorescent protein (GFP) allows gene and protein expression patterns to be easily visualized in a live animal. Although the worm has a small number of cells (959 somatic cells in the adult), many cell types found in mammals are conserved in the worm, including nerve (302 neurons), muscle, excretory, and gut cells.

Two significant events occurred in 1998 that propelled *C. elegans* as a frontline model organism to impact drug discovery research: *C. elegans* became the first multicellular organism with a fully sequenced genome, and a phenomenon known as RNA interference (RNAi) was shown to work very efficiently in the worm. Indeed, Andy Fire's laboratory discovered that injection of double-stranded (ds) RNA molecules can block gene function via degradation of the targeted mRNA. With the entire worm genome sequence in hand and the ability to selectively inactivate any gene of interest by RNAi, rapid reverse genetic experiments became feasible. RNAi initially utilized injection of dsRNA into the worm gonad, but it was quickly discovered that worms can take up dsRNA via soaking or by feeding on *E. coli* engineered to express the dsRNA molecules. RNAi by feeding became a relatively inexpensive way to inactivate a gene of interest and, more importantly, opened the way for rapidly inactivating numerous genes (individually or simultaneously) for loss-of-function studies. Researchers have since created reusable RNAi libraries of bacterial strains. One such library currently covers ~86% of the entire worm genome and has been used in genome-wide RNAi screens to identify genes involved in fat metabolism, embryonic development, and aging.

As in *C. elegans*, RNAi has been an effective way to speed up functional analysis in *Drosophila*. While the primary method is to inject dsRNA into the embryo or to transfect *Drosophila* S2 cells in culture, researchers have developed methods combining P-element insertions and GAL4/UAS (upstream activating sequence) driver lines (see Sect. 3 on ''Development of Disease Models'' for a description of these lines) to generate flies that express dsRNA in a spatial or temporal manner. Thus, the impact of inactivating a developmentally essential gene in the adult or inactivating a gene in an individual tissue can now be studied. This technique opens the door for systematic RNAi analysis in *Drosophila*, although the need to maintain fly stocks and the difficulty in devising high-throughput screens currently prevent the same rapid whole-genome analyses that are possible with *C. elegans*.

The real power of working with lower model organisms is in combining the facile methods for reverse genetics (gene KOs, RNAi) and transgenics (genetic complementation, humanization), with classical genetics (suppressor/enhancer screens, epistasis analysis, synthetic lethality) and cell and whole-organism biology, as will be illustrated later in this chapter.

2.2 Lower Vertebrates

While yeast and invertebrates together share many of the features that are central to human biology (morphogenesis,

cell cycle, apoptosis, sexual reproduction, neurobiology, muscle development, metabolism, behavior, aging), zebrafish (*D. rerio*) expands the human connection to encompass vertebrate organogenesis, bone, heart, and blood development and physiology. Genome sequencing efforts are still ongoing for zebrafish, but it is already evident that large chromosomal regions are syntenic between zebrafish and humans, and it is projected that nearly all human proteins will have orthologs in zebrafish with 85% average protein homology.

Zebrafish has been used as a model organism since the 1970s when researchers at the University of Oregon began using it as a neuronal model. Before that time, it was primarily used in toxicology studies and in studies of development with little focus on it as an exploitable genetic system. However, unlike many fish, zebrafish exists as a diploid rather than as a triploid or tetraploid, and is therefore more readily amenable to genetic manipulation. Zebrafish are small (3 cm) in size, develop rapidly (freely swimming, fully formed fish in 4 days), and are fertilized externally, allowing synchronized studies. Like *C. elegans*, zebrafish embryos can grow in a 96-well format and are transparent, allowing the use of transcriptional/translational fluorescent reporters. However, unlike *C. elegans*, zebrafish are much more permeable to small molecules. They are also amenable to transient gene overexpression and gene knockdown studies in the embryo via injection of mRNA or antisense morpholino oligonucleotides respectively making reverse genetic studies very straightforward and avoiding the need to maintain actively growing stocks. While zebrafish offer many advantages for drug discovery research, there are some disadvantages: the generation time (3 months) is no shorter than that of the mouse, and gene targeting via homologous recombination is not possible at the moment. However, researchers have shown that cultured embryonic cells can undergo homologous recombination *in vitro*, hence, gene knockouts (KOs) should theoretically be possible.

2.3 Rodents

Moving up the evolutionary tree brings us to the mouse (*M. musculus*), which is regarded as the premier model organism for human therapeutic studies. It is, of course, a mammal with physiological processes (major organs, skeletal structure, and mode of reproduction) very similar to humans. The mouse genome shares high similarity with that of humans in terms of size and gene content, with a significant degree of gene synteny. In addition, it features a well-understood genetic system with many inbred mutant strains available and with facile genetic manipulation techniques. Biomedical and pharmaceutical researchers have relied on the mouse for many years as the workhorse for studying gene functions and for validating therapeutic targets *in vivo*. Gene deletion (also known as gene targeting) and gene addition technologies have been used extensively in the mouse to correlate a particular gene with the underlying pathophysiology of a disease. These types of techniques also allow one to predict whether modulation of a specific protein *in vivo* provides a desired therapeutic effect, and, consequently, to anticipate the effect of an agonist or antagonist compound, and recognize potential on-target or off-target side effects of such agents. In addition, transgenic mouse models (in addition to transgenic rats) are often used

to support the development of compounds in terms of understanding or predicting efficacy, toxicity, and drug metabolism.

The types of mouse models utilized in biomedical and drug discovery research include conventional gene KOs (complete loss of mouse gene function), knockins (KIs; replacement of the mouse gene with human cDNA or variant under control of the endogenous mouse promoter), transgenic overexpressors (expression of human cDNA or variant in a specific spatiotemporal manner, typically with a tissue-specific promoter; amenable to both mouse and rat models), and conditional KOs or conditional transgenics (offering complete spatiotemporal control of gene expression in the adult animal). Each has unique advantages and disadvantages, and the choice of model depends largely on the intended application and the questions being addressed. Another important factor is to engineer mice with the appropriate genetic background for phenotypic analysis. A few examples of how these different types of models can be used to impact various stages of drug discovery and development will be discussed later in this chapter.

While in recent years there has been a major focus on generating large numbers of conventional mouse KOs targeting genes of interest for understanding various diseases, it has become clear that there is a growing need for more sophisticated types of models. The ideal model is one that employs some form of gene switch technology, that is, a model in which one can control where and when a gene is switched on or off by administering a small-molecule inducer. These so-called ''conditional KOs'' and ''inducible transgenic overexpressors'' provide several distinct advantages over more conventional models: (1) they are more relevant to disease manifestation, offering inducibility and the potential for reversibility of a phenotype; (2) they allow one to assess gene function in an adult mouse, often in combination with other disease states (e.g. diet-induced obesity); (3) they are better models of drug action (i.e. a KO from the start of development may not simulate the effect of an antagonist administered to the adult); (4) they can overcome situations of embryonic or postnatal lethality (in which case a conventional model cannot be easily obtained); and (5) they can overcome the potential issue of functional compensation during development, in which case misleading phenotypic information can be generated.

A number of conditional methods are available. These include methods based on the tetracycline promoter/inducer (Tet-ON and Tet-OFF) system for regulated transgene expression, and methods that utilize recombinogenic loxP repeat sequences and regulated cre recombinase (cre–lox system) for conditional gene KOs. The cre–lox system has been used successfully to create null mutations in specific tissues and cell types. In this system, mice containing ''floxed'' alleles (i.e. alleles flanked with loxP sites) are crossed with mice containing cre expressed in the desired cell or tissue type, and the resulting gene KO reflects the expression characteristics of the promoter used to drive cre expression. Alternatively, cre can be expressed under the control of a promoter that is inactive in the absence of a small-molecule inducer, and a KO is induced wherever and whenever the inducer is administered. In addition to controlling cre expression at the transcriptional level, some systems involve the use of a ubiquitously expressed fusion protein, consisting of cre linked to a mutant form of the ligand (tamoxifen) binding domain

of the estrogen receptor (cre-ER). In the absence of tamoxifen, the cre-ER protein is sequestered in an inactive form bound to a heat shock protein, but it is activated posttranslationally by association with tamoxifen. Given the great advantages of conditional KO and inducible transgenic systems, many other variations on these basic themes are under development in several laboratories.

A potentially powerful approach for gene targeting in rodents is to exploit RNA interference. Gene knockdown has been achieved in adult mice utilizing vector-mediated or transgenically supplied siRNAs (short interfering RNAs) and shRNAs (short hairpin RNAs). Also, transgenically expressed siRNA has been used for gene silencing in rats, where embryonic stem (ES) cell technology has not yet been established to produce KO animals. While there are still considerable caveats and technical hurdles to overcome before adopting such methods for routine mouse model generation, RNAi combined with inducible transgenic technology has the potential to radically change the way rodents (and possibly other mammals) are exploited to understand gene function *in vivo*.

Another very powerful technique is to replace the targeted gene with a reporter gene (e.g. lacZ or luciferase) under control of the endogenous mouse promoter, allowing one to deduce the native expression of the targeted gene. Similarly, the reporter gene can be linked to an overexpressed transgene allowing one to confirm its appropriate expression in the desired cell type or tissue.

The impact of transgenic mice on target selection and validation is limited by the time and resources required to engineer, breed, and phenotypically evaluate large numbers of recombinant strains. There is the constant pressure of timeliness of delivering phenotypic data to support a decision about whether or not to launch a compound screen against a particular target. Certain advances in technology have helped to streamline and accelerate the rate limiting steps. These include (1) construction of gene targeting vectors by recombination (in some cases based on bacterial artificial chromosomes), (2) automated analysis of recombinant ES cells to identify clones containing targeted alleles, and (3) the use of tetraploid embryo complementation to generate mice fully derived from targeted ES cells eliminating the subsequent breeding steps required to obtain chimeras, and to screen for germ-line transmission of targeted alleles. However, each of these advances comes with factors that may limit their practical application to the drug discovery process, such as sacrificing a preferred genetic background for speed. The bottom line is that transgenic mouse model generation, genotyping, breeding and phenotyping require a major investment in specialized personnel, time, and money. However, the impact of these models is so significant that transgenic rodents play a major role in therapeutic target identification, drug candidate selection, and product development.

We will now concentrate on various aspects of drug discovery and development where model organisms are providing an impact, and cite a few interesting examples along the way.

3 Development of Disease Models

Genetic manipulation of model organisms is fundamental to the creation of many types of disease models that are used extensively in drug discovery. Transgenic technology in the mouse has given rise

to several models that recapitulate human diseases, and have been used to advance our understanding of pathophysiologies and to enable new methods of drug treatment to be explored.

One of the first models to be developed was a transgenic mouse expressing an activated v-Ha-ras oncogene under control of the mouse mammary tumor virus promoter (the famous ''OncoMouse''), which is prone to develop tumors. Since then, more sophisticated applications of transgenic technology have contributed to our understanding of the functions of oncogenes and tumor suppressor genes, as well as the mechanisms of metastasis, angiogenesis, and tumor maintenance and regression. For example, inducible expression of oncogenic Ras (an *H-RasV12G* transgene) in a mouse lacking the *INK4a* tumor suppressor gene results in an inducible melanoma model, providing genetic evidence that this allele plays a critical role in tumorigenesis and maintenance of solid tumors.

In the field of cardiovascular diseases, there are transgenic mouse models for hypertension, obesity, insulin resistance, lipoprotein regulation, and atherosclerosis. An example is the ApoE homozygous KO (−/−) mouse, which develops atherosclerotic lesions histologically similar to the lesions observed in humans. Further, ApoE −/− in combination with homozygous mutations in the low-density lipoprotein (LDL) receptor gene enhances the atherosclerotic phenotype.

Transgenic mouse models have been developed for Alzheimer's disease (AD), for example, mice engineered to overexpress human APP. These mice display AD-like neuropathologies (beta-amyloid peptide deposits, neuritic plaques, synaptic loss, neurodegeneration) and behavioral phenotypes (memory loss). They have been used to investigate new therapeutic approaches that would be impossible to pursue in humans due to the extreme difficulty in obtaining normal and diseased brain tissue during the course of disease progression. In addition, a PDAPP transgenic mouse model was created which expresses a disease-linked mutant form of human APP (which in humans results in increased production of the Abeta42 peptide found in amyloid plaques) and develops neuropathological signs of AD over time. Young PDAPP mice immunized with Abeta42 fail to develop signs of disease, whereas mice immunized at an older age show reduced disease progression, opening up the intriguing possibility of a vaccine approach for preventing or treating AD.

While transgenic technologies in the mouse allow one to closely incarnate the human condition, lower model organisms also play an important role in disease model development. However, drawing meaningful parallels with human biology can often be a challenge in these systems. Successfully recapitulating specific physiological aspects of human diseases in worm, fly, or fish has some clear advantages in terms of speed; plus these models are amenable to powerful platform genetic screens for further target identification and pathway analysis. Phenotypic suppression in specific disease models in worm, fly, or fish that are relevant to human biology, can reveal proteins whose human counterparts may turn out to be excellent targets for therapeutic intervention.

Advances in *Drosophila* genetics have enabled parallels between humans and flies to be exploited more effectively and more rapidly. One approach to generate disease models in the fly is to use the GAL4-UAS system, which allows the selective activation of any cloned gene

in a variety of tissue- and cell-specific patterns. This system utilizes a panel of ''driver'' fly lines, each of which expresses the yeast GAL4 transcriptional activator under a different tissue- or cell-specific promoter. A second transgenic fly line is generated in which the gene of interest is placed downstream of multiple DNA binding sites for *GAL4-UAS*. Using simple genetic crosses, transgenic flies can then express the target gene in the desired pattern by mating with driver fly stocks covering a range of tissues. This method has now been adapted to zebrafish, so one can easily engineer disease models in which overexpression of a gene induces disease in fly or fish (e.g. tumorigenesis, neurological defects).

The ''FLP-out technique'' in *Drosophila* (involving the FLP/FRT system of yeast) is another powerful way to achieve heritable loss of function in target tissues. The FLP/FRT system also provides a way to screen conditionally in target tissues for mutations that would normally be lethal or yield complex phenotypes. For example, the FLP/FRT system can be used to make the eye of the fly homozygous for a given mutation, while the rest of the animal has wild-type gene function. This technique allows genetic screens (e.g. mosaic screens) for mutations in genes involved in essential pathways, such as synaptic transmission or tumorigenesis. This approach is particularly useful when conducting suppressor/enhancer or gain-of-function screens involving phenotypes produced by tissue-specific overexpression of a human gene of interest. A tetracycline-inducible expression system has also been developed for transgenic research in the fly. Using tetracycline-inducible transactivators (Tet-ON), inclusion of low levels of the inducer drug doxycycline in normal fly food leads to rapid induction of target transgenes in adults, larvae, and embryos. Combining this with the GAL4-UAS system produces robust, spatially and temporally regulated transgene induction.

Drosophila is proving to be an excellent model for cancer research, with over 30 fly genes identified, which, when mutated, cause tumor growth or overproliferation; several have mammalian counterparts and functional conservation in mammals. One such gene, *Lats/Warts*, was identified using the FLP/FRT system in a screen for tumor suppressors in the fly, where somatic cell mutations result in tumor outgrowths. The phenotype of mutant *lats* flies can be rescued by the human *LATS1* gene indicating functional conservation. *Lats1*-deficient mice were shown to develop soft tissue sarcomas and ovarian tumors, and are sensitive to carcinogens. In addition, adenovirus-mediated overexpression of human *LATS* causes a decrease in proliferation in a variety of tumor cell lines. Subsequent work identified the *lats* gene product as a novel cell cycle mediator that inhibits CDK1 activity leading to G2/M arrest and promotes apoptosis through induction of Bax. Given that *Lats* is a tumor suppressor, it is not a drug target; however, *lats* mutants could be used in suppressor screens to identify targets that, when inactivated, prevent tumor outgrowth in the fly.

Given the critical need to identify more effective treatments for Alzheimer's (AD) and Parkinson's (PD) diseases, numerous laboratories have created models for these diseases. Mice, worms, flies, and zebrafish have been used to overexpress human tau, a protein that forms neurofibrillary tangles in the brains of AD patients and others with neurodegenerative diseases. In each organism, a clear phenotype

was observed that was consistent with what is known about tauopathies. For instance, in *Drosophila* and *C. elegans*, neuronal loss was observed, and tau accumulated in aggregates in the *C. elegans* model. In zebrafish, cytoskeletal disruptions that resembled neurofibrillary tangles were observed.

A Parkinson's disease model has been established in mice, *Drosophila* and *C. elegans* in which α-synuclein is overexpressed from a dopanergic promoter. In all three organisms, motor deficits and neuronal and dendritic loss are observed, similar to those observed in patients with PD, thus faithfully recapitulating the essential features of the human disorder. Genetic screens in worms or flies and microarray experiments with the mouse, fly, or worm models should be useful to better understand the disease and identify novel therapeutic targets for PD.

The ability to create sophisticated models in a simple vertebrate like zebrafish offers great potential. These models will in most cases mimic human diseases better than the worm or fly models will, and the ability to conduct genetic screens offers a clear advantage for zebrafish over the mouse. Besides the AD model mentioned above, cardiomyopathy, muscular dystrophy, bacterial pathogenesis, and cancer models have been created in zebrafish. One cardiomyopathy model utilizes a loss-of-function mutation in the TNNT2 gene which, when mutated in humans, causes familial cardiomyopathy. While cancer in zebrafish has been studied for many years, the first cancer model was recently established in zebrafish in which the mouse *c-Myc* transgene was expressed from a lymphocyte-specific promoter (Rag2) resulting in T-cell acute lymphoblastic leukemia.

4 Identification of Therapeutic Targets

Genetic screens in model organisms are often used to identify new therapeutic targets. Nonmammalian models are the systems mainly exploited for this purpose, although forward genetic screens in mice (*via* ENU [ethylnitrosourea] mutagenesis) or in ES cells have been successful in revealing genes/proteins of potential therapeutic interest. We will focus here on genetic screens in lower species. To be successful with this type of approach, one needs to begin with either a good disease model or initial knowledge that the molecular pathway underlying the disease is conserved in the organism of choice.

Forward genetic screens require no *a priori* knowledge of the genes involved and will identify genes coding for proteins of any class. In this approach, the model organism is subjected to chemical or physical mutagenesis (or P-element insertion in *Drosophila*) followed by a screen to identify mutants with the desired phenotype. Once identified, the mutations are mapped and the genes isolated. While forward genetic approaches are very powerful, considerable time and resources are needed to map the mutations and identify the genes in multicellular organisms despite recent advances in Single Nucleotide Polymorphism (SNP) mapping.

One recent phenotype-driven approach in the fly revealed an interesting protein, the product of a gene called *Indy*, whose human counterpart may be of interest as a drug target. Analysis of a collection of mutant *Drosophila* obtained by P-element insertions, identified five lines with >50% increase in life span. All P-element insertions were found to be in the same gene designated *Indy*, for ''I'm Not Dead Yet.'' The maximum effect was

seen in heterozygous P/+ flies, less in homozygous P/P flies, and an opposite effect (shortened life span) was seen in P/deletion flies, suggesting that the level of *Indy* protein is critical for life span extension. *Indy* encodes a sodium-coupled citrate transporter (11 transmembrane protein) expressed in the *Drosophila* fat body that is involved in storage of fat, glycogen, and protein, equivalent to the mammalian liver. There are two human orthologs of *Indy*, and orthologs from mouse, rat, and worm have also been cloned. The hypothesis is that *Indy* mutations create a metabolic state that mimics moderate caloric restriction; therefore, modulation of the human protein(s) may be an effective therapeutic approach for tackling obesity.

Until fairly recently, the only approach to a genetic screen was through forward genetics. However, with gene sequences in hand, reverse genetic techniques can be used where the gene of interest is selectively inactivated by deletion in the genome (yeast, fly, and mouse), RNAi (worm and fly) or antisense oligonucleotides (zebrafish). Today, reverse genetics can be applied on a whole-genome scale in yeast using a library of yeast strains, each with a single gene deleted, or in *C. elegans* using a whole-genome RNAi library expressed in *E. coli*. The power of this approach is that once the screen is completed, the identity of the gene is known. This does not mean that traditional forward genetic approaches are no longer useful as gene inactivation methods cannot be used to identify gain-of-function mutations, and in the worm, the nervous system is somewhat refractory to RNAi even when RNAi-hypersensitive mutants are utilized.

A recent genome-wide RNAi analysis in *C. elegans* aimed at identifying fat regulatory genes, illustrates how the worm can be used to identify novel targets for tackling obesity. In this screen, the vital dye Nile Red was used to stain fat after RNAi of each *C. elegans* gene. Numerous genes were identified that increased or decreased fat storage, including genes in the insulin, serotonin, or tubby signaling pathways. By simply identifying the human orthologs of these genes, and selecting those that encode tractable drug targets (e.g. enzymes, transporters, ion channels, GPCRs, and nuclear receptors), a fairly short list of potential drug targets can be obtained. Literature searches with the human ortholog and all model organism orthologs to this protein can help to narrow the candidates further. Additional target validation studies can then be carried out with selected targets. A process for using genomic-scale RNAi in *C. elegans* to identify human proteins as potential drug targets is shown in Fig. 2.

Given that yeast is a single-cell organism, much of its application to target identification has focused on the cell cycle and conserved cellular pathways. *S. cerevisiae* clearly has its place in drug discovery, for example, as a platform for heterologous protein expression, functional cell-based assays, structure-function analysis of human proteins, and two-hybrid screening for protein–protein interactions. However, the fact that yeast lacks many of the biological processes involved in complex human diseases that require multicellularity as well as highly differentiated cell types (such as AD, schizophrenia, asthma, and osteoarthritis), limits its use in the identification and validation of most drug targets. Notwithstanding this, given that many molecular pathways are conserved from yeast to man, the sophisticated and ultrarapid molecular and genetic techniques available in yeast can be utilized to facilitate pathway dissection of those targets that have orthologs in yeast.

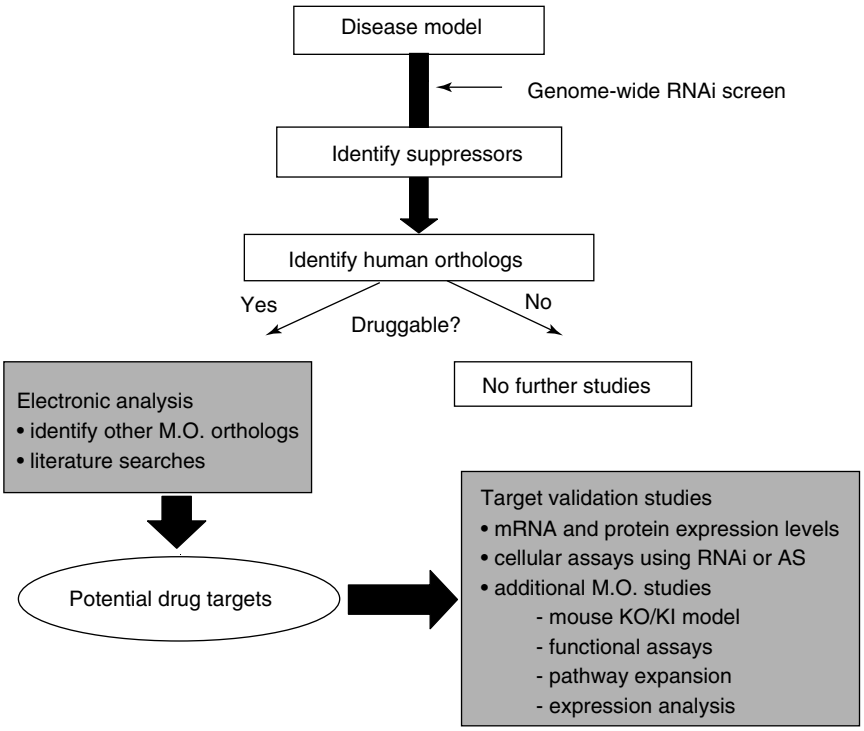

Fig. 2 Target identification process in *C. elegans* using genomic-scale RNAi. AS, antisense oligonucleotides; MO, model organism; KO, knockout; KI, knockin.

Another strategy for novel target discovery is to identify the molecular target of an existing drug or compound that has a desired physiological effect in animals or humans, but whose mechanism of action (MOA) is unknown (i.e. ''orphan'' compounds). Knowledge of the target of any compound is likely to accelerate the discovery of new medicines with a similar or related MOA. The purpose of a genetic-based MOA screen, typically implemented in yeast or worm is not just to understand the physiological effects of drug treatment in a worm or yeast cell, but rather, to use the model organisms as a platform for generating drug-resistant or drug-hypersensitive mutants that, through genetic characterization, may reveal proteins involved in mediating drug sensitivity. This approach offers the possibility of identifying the direct molecular target(s) of the drug, other proteins in the pathway leading to drug sensitivity, as well as proteins that mediate drug uptake, efflux, and metabolism. The first step, of course, is to determine whether the compound of interest induces a scorable phenotype (such as death) that can be used as the basis for screening or selecting mutants. In one such published example, fluoxetine (Prozac)-resistant mutants of *C. elegans* were isolated. The mutants define seven genes, two of which were genetically characterized and found to encode members of a family of novel 12-transmembrane proteins of unknown function. The functions of the orthologous human proteins may offer some insight into the MOA of fluoxetine.

Perhaps the best example of successful MOA studies that revealed proteins directly involved in drug binding and drug action, and in which the data obtained in a model organism were quickly translated to humans, are the studies conducted in yeast in the early 1990s that identified the direct targets and downstream signaling pathways for the immunosuppressive drugs rapamycin, FK506, and cyclosporin A. These drugs had been used to prevent organ rejection in transplant recipients, and the MOA studies in yeast took advantage of the fact that these drugs were originally isolated as natural products with antifungal activity. The hypothesis was that understanding the mechanism by which these compounds kill a yeast cell might reveal something about how they affected T-cell function in humans. Yeast mutants resistant to each drug were isolated, and the mutated genes were found to encode the proteins cyclophilin (shown to be a cyclosporin-binding protein) and FKBP12 (an FK506-binding protein that also binds rapamycin), collectively referred to as immunophilins. These proteins are enzymes that catalyze the folding of other proteins, and although drug binding specifically inhibits their enzymatic activity *in vitro*, this loss of function does not account for the cellular action of the drugs. Instead, the pharmacological effects of these drugs are derived from the formation of specific cyclophilin or FKBP12-drug complexes that interact with other downstream cellular proteins, namely, calcineurins and TORs, (targets of rapamycin). Thus, the immunophilins act as molecular chaperones for these drugs, delivering them to other sites of action in the cell, target proteins whose functions have now been well characterized. For example, the mammalian TORs are conserved PI-3-kinases that act as central regulators of cell growth, and because of this, the human counterparts are being investigated as targets for cancer. In all cases, the key proteins in the signaling pathways that govern the MOA of these drugs are highly conserved between yeast and man, and our current understanding of how these drugs work owes a great deal to some elegant genetic studies that originated in the simple baker's yeast.

These types of studies are now greatly facilitated by the availability of genomic-scale gene inactivation technologies. Having a library of >6000 yeast KO strains, and an RNAi library arrayed in *E. coli* covering all *C. elegans* genes, enables automated screening for drug-resistant or drug-hypersensitive mutants, and to then instantly know the identity of the gene, which, when inactivated, gives rise to the phenotype.

5 Functional Validation of Targets

Transgenic mouse models (i.e. gene KOs and overexpression transgenics) offer the greatest prospect for correlating a molecular target with underlying disease pathophysiology, and thus play an important role in therapeutic target selection and early validation. These models provide biological evidence in a mammal for or against the causal relationship between specific genes and disease. Having evidence of a link to disease, or to a phenotype (e.g. blood pressure), which, if modulated, could result in alleviation of disease symptoms, is usually a prerequisite to launching a high-throughput screening or subsequent optimization phase of a compound that involves a major investment in chemistry resources.

There are many examples in the literature, too many to list here, where

transgenic mouse models have been used to validate a particular human protein as a target for drug discovery. Recent published examples from our GlaxoSmithKline team include vanilloid receptor-1 (validated as a target for pain associated with inflammation), uncoupling protein-3 (validated as a target for obesity), the $GABA_{B1}$ receptor subtype (validated as a target for psychiatric and neurological disorders including epilepsy), and urotensin-II receptor (validated as a target for hypertension). There are also other excellent recent reviews on the subject that provide numerous examples.

Since a major challenge currently facing biomedical and pharmaceutical researchers is to extract from the human genome those targets with the greatest potential for therapeutic intervention, there are large-scale efforts underway to systematically KO the druggable genome in the mouse. This is being combined with comprehensive platform phenotyping (histopathology, serum biochemistry, clinical pathology, behavior, etc.) to reveal unexpected phenotypes relevant to human disease. A recent survey of the literature indicated that among those GPCRs that have been knocked out in the mouse, more than 50% had phenotypes that contributed (or would have contributed) to target selection and validation. This percentage increases significantly upon provocative challenge in these models. The next major hurdle is to interpret the avalanche of available *in vivo* biological data from hundreds of mouse KOs, and to focus screening and chemistry resources appropriately around newly validated and previously unexploited targets.

In support of this approach, a recent retrospective analysis of the targets for the top-selling one hundred drugs revealed that there is a strong correlation between mutant phenotypes in the mouse and known drug efficacy in man, that is, many mutant phenotypes have been informative in terms of understanding protein function and deciding pharmaceutical utility, and looking back, were predictive of the therapeutic effect of drugs developed against those particular targets. However, prospectively, not all conventional KOs were equally informative. Thus, validating a protein's role in disease often requires the generation and analysis of more advanced types of mouse models (e.g. tissue-specific conditional KOs and inducible transgenic overexpressors) as well as the use of other genomic approaches (e.g. microarray and proteomic platform technologies).

6 Identification of Pathways

Oftentimes, disease or disease susceptibility genes identified in human genetic studies encode proteins that are not chemically tractable, and/or the disease state is due to a loss-of-function mutation that cannot be reversed with a drug (e.g. ApoE, parkin, huntingtin, polycystic kidney disease (PKD1/2)). In these instances, experiments need to be undertaken to uncover the pathway in which the gene/protein functions with the goal of identifying a suitable drug target and obtaining a better understanding of the underlying cause and progression of the disease. Typically, yeast two-hybrid, proteomic, and transcriptomic studies are undertaken with the human gene to identify binding partners or genes that are up- or downregulated in the disease state. However, if an orthologous gene exists in a simple model organism, genetic studies can be undertaken to identify other genes, which, when inactivated, reverse a

particular phenotype observed in that organism. This type of pathway analysis can also be useful when the target is tractable, but there is poor understanding of the pathway. This may identify substrates or upstream activators, thus supporting high-throughput assay development.

Initially, experiments are conducted to determine if there is a phenotype associated with inactivating or overexpressing the disease gene. If a phenotype is observed, a genetic suppressor screen can be conducted to identify suppressors of the phenotype. The advantage of this approach is that a gene is identified that is able to reverse the disease state when inactivated. If a suppressor screen is not feasible, one can couple other genomic technologies (such as the yeast two-hybrid method or proteomic and transcriptomic expression analysis) with studies in model organisms, whereby genes identified by the genomic approaches are inactivated or activated in the disease model to identify those genes that are able to suppress the disease state.

Polycystic kidney disease, a common heritable disease affecting 1 in 1000 individuals, provides a good example. Mutations in either the PKD1 or PKD2 genes cause PKD in humans, but the function of these genes is largely unknown. Studies in *C. elegans* demonstrated that the two *C. elegans* orthologs, lov-1 and pkd-2, are required for proper male sensory behavior, and are localized to male sensory neurons. This information led researchers to examine the colocalization of the worm and mammalian PKD1 and PKD2 proteins in renal epithelial cells where they found that each localizes to focal adhesions indicating a common sensory function. Given that mutations in both lov-1 and pkd-2 exist, researchers are now poised to elucidate the pathway through the identification of suppressors of the male sensory behavioral phenotype in *C. elegans*.

7 Development of Functional Assays

The ability to complement a defect in a model organism gene through expression of a human gene (as cDNA), can often form the basis of a functional assay that can serve multiple purposes in drug discovery, including target validation, compound screening, and structure-function analyses. In the mouse, replacing a gene with its human counterpart is particularly useful when compounds have pronounced selectivity for the human protein. By generating such a ''humanized'' (KI) mouse model, one can use the model for target validation and for compound progression (see below in Sect. 8).

The advantages of creating ''humanized'' models in other model organisms are primarily speed and throughput. It takes a considerable amount of time to generate a humanized mouse model (12–18 months), but in a simpler organism, a similar model can take as little as 2 to 3 weeks in yeast, or 2 to 3 months in worm, fly, or zebrafish. Once the model is established, it can be used to test thousands of compounds compared to only a handful in the mouse.

The ease with which one can delete an entire gene using homologous recombination in yeast, makes yeast especially useful for complementation studies with human genes. Many human genes have been successfully studied in these types of experiments including several cell cycle genes (CDKs, PLK, CDC14, ATM and survivin), numerous members of the MAPK cascade (JNK1, p38, and PAK1), and various enzymes (LAG1, PDE4, PDE7,

FKBPs and cyclophilins, to name but a few). Yeast is also extremely useful for structure-function analyses, wherein individual codons in the human cDNA are altered and the ability of the mutants to functionally complement the yeast gene is readily determined.

The speed with which one can generate the mutants, obtain stably transformed yeast, and perform the cellular assays represents a very significant advantage compared to the use of mammalian cells and other model organisms. The human cDNA can be expressed at virtually any level in yeast using a variety of promoters and expression vectors, or via targeted integration of the human cDNA in the yeast genome (as a gene replacement) using homologous recombination. Coupled with a selective compound, mutagenesis studies can facilitate structure-activity relationship (SAR) studies particularly where a crystal structure is not available.

8 Compound Identification and Progression

With the exception of functional cell-based assays engineered in yeast cells, models organisms are not typically used as a platform for high-throughput drug screens. However, they can be particularly useful for secondary and tertiary screens to confirm that compounds function *in vivo*, as well as to reveal off-target side effects or toxicities.

Yeast has been successfully used in screening compounds with GPCRs where the integral membrane nature of the receptor makes purification impossible and where overexpression in mammalian cells sometimes causes endogenous GPCR signaling. In this system, the yeast mating pathway has been used to identify agonists or antagonists of human GPCRs. Heterothallic haploid *S. cerevisiae* cells exist as mitotically stable MAT**a** or MATα cells, where MAT**a** cells express **a** factor and the α-factor receptor (Ste2p), and MATα cells express α-factor and the **a** factor receptor (Ste3p). Upon appropriate mating factor binding, the receptor activates the heterotrimeric G-protein that in turn activates an MAPK signaling cascade, thereby leading to transcriptional activation of a variety of genes and to cell cycle arrest. When *STE2* or *STE3* are replaced with a human GPCR expressed from a plasmid, the pathway can be activated by an exogenously added ligand. Such assays also rely on deletion of the *FAR1* gene to prevent cell cycle arrest upon receptor activation, and utilization of an *FUS1-HIS3* reporter for growth selection in the absence of histidine when the mating pathway is activated. The existence of only two GPCRs controlling the mating pathway in yeast is a major advantage since deletion of STE2 or STE3 in a haploid cell results in a null receptor background, facilitating the assay readout. Besides serving as a platform to identify antagonists of a ligand-receptor interaction, this elegant system can also be used to screen for agonists (or surrogate agonists) of an orphan receptor when no ligand is available. While yeast has been a very effective tool to facilitate such GPCR drug discovery programs, the yeast cell wall renders the cells impermeable to some compounds. For this reason, yeast-based assays for intracellular targets are used only when no other option is available, and must then involve the use of hyperpermeable mutants deficient in ergosterol biosynthesis.

On the other hand, zebrafish holds the most promise for use in medium throughput compound screening. Zebrafish are relatively easy to grow in a 96-well format,

tolerate dimethyl sulphoxide (DMSO), and are highly permeable to compounds. In addition, the higher degree of conservation between zebrafish and human proteins may avoid the need to create humanized strains of zebrafish. In a recent paper, zebrafish were treated with 100 small molecules to assess whether they could be used to predict long QT syndrome, a serious cardiac clinical side effect. Zebrafish contain HERG-related K^+ channels, which, in mammals are known to mediate such cardiac liabilities. Using a simple optical videoimaging of the beating heart in young embryos to measure cardiotoxic effects, most of the compounds (22/23) that cause QT prolongation in humans were found to cause bradycardia and atrial ventricular block in zebrafish, indicating that zebrafish can be used to predict QT prolongation. These data suggest that if a suitable assay can be devised, zebrafish can be used for testing drugs for other toxic effects and thereby support the development of compounds.

Humanized mice have also been exploited as tools to support early stages of development of compounds, specifically in cases in which lead compounds display significant species selectivity toward the human target; that is, they exhibit a higher affinity for the human target than for the murine counterpart. A good example is the targeted replacement of the mouse chemokine receptor (CCR2) with its human ortholog (CCR2B). CCR2B has been considered a target for atherosclerosis supported by the phenotype of KO mice lacking either the receptor or its ligand (i.e. impaired monocyte recruitment and protection against development of atherosclerotic plaques). Humanized CCR2B KI mice are viable, appear normal, and can elicit a normal inflammatory response to intraperitoneal injection of thioglycollate (peritonitis model). Macrophages from the KI mice respond to the human MCP-1 ligand (monocyte chemoattractant protein-1) and to its murine counterpart (JE) in *in vitro* chemotaxis assays in a manner similar to human peripheral blood monocytes. Furthermore, human-selective CCR2B antagonists show an enhanced potency for blocking the cellular response to human MCP-1 versus the response to murine JE. The KI mouse provides the ability to test hCCR2B antagonists in a series of inflammatory disease models induced experimentally (such as the peritonitis model) or created genetically (such as an atherosclerosis model created by crossing onto an ApoE – /–background).

Mouse KOs, Kis, and transgenic overexpressors are also useful for investigating drug safety, revealing mechanisms of toxicity, and measuring drug metabolism and pharmacokinetic parameters. Compounds displaying toxicity in other animals can be tested in KO mice lacking the target (as well as in wild-type controls) to determine whether the observed toxicity is target-mediated or is due to lack of selectivity (''off-target'' effects). Further, mice expressing reporter genes that are responsive to toxic insult or are part of known stress-induced pathways are useful in identifying mechanisms of toxicity. Mouse models sensitized to respond rapidly to carcinogens (e.g. p53 +/− mice) have also been extremely valuable in the assessment of the toxicity of compounds under development. Lastly, human drug metabolism genes have been introduced into mice in order to create models that more closely mimic the human drug response (e.g. human cytochrome P450 4B1, CYP4B1), and mutants lacking endogenous P450s have been used to study the role of these proteins in drug metabolism.

9 Summary and Future Perspective

The perfect model organism to support biomedical and pharmaceutical research would be a mammal with exquisite genetics and a completely sequenced genome, be amenable to genome-scale gene inactivation, have a rapid generation time, be transparent, grow in a 96-well format, and be drug permeable. However, since no model organism possesses all of these qualities, we must therefore continue to employ a repertoire of different organisms, each with specific advantages, and choose the most appropriate organism in which to investigate the key biological questions.

In the case of yeast, rapid growth and homologous recombination make it particularly useful for functional assay development to support pathway dissection and structure-function studies. While not a focus of this chapter, the rapid doubling time and the ability to scale up cultures using fermentors, has led to yeast being used extensively to overexpress human proteins for subsequent use as protein therapeutics or in biochemical assays and structural studies following protein purification. In addition, yeast has served as a workhorse to identify protein–protein interactions using the yeast two-hybrid assay.

In *Drosophila*, sophisticated genetic techniques like the GAL4-UAS and the FLP/FRT systems have made it particularly useful for establishing disease models to support target identification and pathway analysis using forward genetics. RNAi coupled to the GAL4-UAS system allows spatial and temporal gene inactivation studies in whole flies to support target validation studies.

Whole-genome RNAi, the ability to grow in a high-throughput format and the transparent nature of *C. elegans*, make it an excellent organism for disease model generation followed by rapid target identification or pathway expansion *via* reverse genetics.

Together, yeast, worms, and flies contain many of the fundamental genes and pathways relevant to human biology, but they lack the complex physiology inherent to higher mammals.

Zebrafish bridges the gap between invertebrates and mammals. Complex disease models coupled with both forward and reverse genetic techniques can be utilized to identify and validate targets, and elucidate pathways in fish. Transparent embryos, high drug permeability, and the ability to grow and treat embryos in microtiter plates allow this organism to be used for identification of compounds and for progression as well.

More relevant *in vivo* biological data in support of target validation typically come from studies in transgenic mice. Utilization of mouse disease models to determine lead compound efficacy provides additional target validation and can reveal toxicity issues or off-target effects. The key to successfully using simple model organisms (yeast, worm, fly, fish) to support target identification and validation is to have reliable mammalian cellular assays and, more importantly, predictive mammalian models to follow up on the findings. Hence, mouse models will continue to play a central role in biomedical and pharmaceutical research.

Future developments in model organism studies will inevitably evolve from additional technology advances leading to faster, cheaper, better, or novel methods to manipulate the organisms discussed in this chapter. As the genomes from more and more species are being fully sequenced, comparative sequence analysis will undergo dramatic progress in the

area of gene function prediction. For the most part, these organisms will not lend themselves to the types of genetic and genomic studies described herein, and will only contribute their genome sequences to furthering biological knowledge. This has been the case for the Japanese pufferfish *Fugu rubripes* whose compact genome has been completely sequenced and shown to comprise large regions of conserved synteny with the human genome. *Fugu*'s genome is being actively analyzed to identify disease-causing genes, to refine gene families into their subfamilies, such as the NHR family and its subgroups, and to validate *in silico* gene predictions from the human genome. However, it is unlikely that *Fugu* will be amenable to the types of manipulations currently possible with zebrafish.

Some organisms exploited during the pregenomic era may resurface as attractive models for gene function understanding, disease modeling or compound profiling. One such example might be the cellular slime mold, *Dictyostelium discoideum*, which has been used extensively to study cell differentiation, signal transduction, cell motility, and other unicellular or multicellular processes. The ongoing sequencing of *Dictyostelium*'s genome by an international consortium and the observation that RNAi gene silencing works in this organism are expected to revitalize its experimental attractiveness. In the meantime, scientists continue to use *Dictyostelium* for specific studies, such as in the recent identification of a gene responsible for lithium resistance that led to uncovering a role for inositol metabolism in bipolar affective disorder.

New biological knowledge and technology breakthroughs may lead to additional organisms joining the ranks of yeast, worm, fruit fly, zebrafish, and mouse as workhorses for the biomedical or pharmaceutical scientists. This is highly anticipated for the rat. Whereas certain genetic manipulations, such as gene KOs *via* homologous recombination in ES cells, are not currently possible, methods for production of KO rats using ENU mutagenesis have been developed. Rat KO models would be most useful since the rat is a fundamental model for pharmacological and toxicological research.

Finally, many new potential drug targets and pathways are predicted to come from genetic studies in man. Identification of disease-associated polymorphic variants in human genes will reveal many unexploitable proteins, and proteins of unknown function. Once again, it will be important to turn to the relatively simple model organisms to investigate protein functions, to reveal the physiological consequences of polymorphisms *in vivo*, to expand pathways, and ultimately to identify and help validate the most appropriate targets for pharmaceutical intervention.

Keywords

Antibiotic Resistance
The ability of the cell to grow in the presence of a chemical (antibiotic) that normally inhibits an essential cell function.

Bacteriophage
A virus that infects bacteria.

Coding Region
The nucleic acid segment that contains the linear arrangement of codons specifying the order of amino acids in the encoded protein.

Codon
A three-nucleotide unit in a molecule of mRNA, which specifies the particular amino acid or stop signal in the mRNA as it undergoes translation.

Fusion Protein
A genetic construct that attaches a coding region of a protein or a portion of a protein to another coding sequence such that the protein formed during translation is a linear combination of the two proteins.

Inducible Promoter
A promoter in which the initiation of transcription by RNA polymerase is controlled by a regulatory protein, which can be activated or inactivated by a chemical or environmental stimulus.

Partition
The usual segregation of the genetic material of the cell into the two daughter cells.

Posttranslational Processing
Changes to a protein made after it is formed by translation, which add other chemical groups (e.g. phosphate, sugar) or cleave the chain to generate the mature native protein.

Promoter
The DNA site at which the RNA polymerase specifically binds to initiate transcription.

Protease
An enzyme that cleaves a peptide bond between amino acids comprising the protein.

Ribosome Binding Site
The region of the mRNA near the site of translation initiation that is important for ribosome recognition.

RNA Secondary Structure
A structure formed within an RNA molecule by bending the molecule such that a series of specific base pairs can form between nearby complementary nucleotides, forming a region that has double-stranded character.

Secretion
The process of controlled release of a protein through the cell membrane.

Virus
An agent naturally able to infect a host cell and bearing genes that allow its complete reproduction within a specific host cell.

The production of a specific protein by recombinant DNA technology entails cloning the gene that encodes the protein from the desired organism, forming a suitable genetic construct such that the gene can be expressed in a host organism, and introduction and maintenance of the construct in the host to allow the production of an adequate yield of functional protein. The ability to take a gene from any organism and express it in adequate quantity in a system permitting the analysis of the structure and function of the protein encoded by the gene has great importance in the research laboratory. Physical and enzymatic features of the protein encoded by a newly discovered gene can be studied, and its functional location in cells or tissues can be determined, in an effort to better define its biological function. Industrial applications include the production of therapeutic and diagnostic proteins having great impact in the field of medicine, and the production of stable bulk enzymes for the food and specialty chemical industries.

1 Introduction to Host–Vector Systems

To produce a specific RNA or protein product in a particular host cell, a suitable DNA construct must be prepared. This section discusses the essential features of expression systems that are widely used for overproduction of proteins for a variety of purposes. The expression system is composed of an expression vector and a specific host cell. Not only is the selection of the ideal expression vector important but the choice of the appropriate host also can affect production efficiency considerably. First, the expression vectors are considered, and then the important attributes of the host are discussed. A number of organisms have been used as hosts for expression of foreign proteins. Since, however, the most complete picture is available for *Escherichia coli*, this prokaryotic organism serves as an example and is discussed in more detail.

Expression vectors usually consist of small, circular plasmids specifically designed with several key features that allow a foreign gene inserted into the plasmid to

be expressed in the host cell. Important elements of the plasmid include (1) an origin of replication, which allows the plasmid to be replicated in the host, (2) a selectable genetic marker, which allows cells bearing the plasmid to preferentially grow on a specifically composed medium, (3) transcription and translation signals recognized by the host cell, and (4) a suitable unique restriction or recombination site located appropriately with regard to the transcription and translation signals, at which the foreign DNA can be introduced. In Sections 2 and 3, the generalized structure typical of many expression vectors is illustrated, and the variation and importance of each of these features in the overall expression system is explained.

2 Components of Plasmid Vectors

2.1 Origin of Replication

The origin of replication of the plasmid is a specific DNA sequence that defines the beginning of the replication of the circular plasmid DNA molecule. Because of its essential function in this event, its structure also limits the frequency with which replication is initiated. Replication frequency defines the copy number of the plasmid (i.e. the number of individual plasmid molecules present in each cell). This parameter, in turn, is important because of the gene dosage effect. If each plasmid carries a copy of the gene, and each copy can give rise to a certain maximal amount of product per unit time, the more copies of the plasmid present in the cell, the greater will be the level of production that can be attained per cell. Of course, there is a limit to this effect, and above a certain level the cell machinery becomes saturated and the increased metabolic burden of maintaining the plasmid overcomes the advantage of gene dosage in the production process.

The most widely used expression vectors for *E. coli* are derived from the origin of replication of the ColEl plasmid and have copy numbers between 10 and 500. The properties of high gene dosage have been used advantageously for the construction of temperature-sensitive copy number control systems in which the copy number can be raised dramatically by increasing the temperature. A typical prokaryotic expression vector is represented in Fig. 1.

Another feature specified by the origin of replication is the compatibility of the plasmid. Since it is sometimes desirable to maintain two distinct plasmids within the same cell, two different origins of replication types would be employed on the two different plasmids. If the two plasmids bear the same type of origin, one eventually will dominate without special selection and the other will be lost from a portion of the cells as the cells grow and divide. This phenomenon is called *incompatibility*, and plasmids with the same origin type are defined as being in the same incompatibility group.

Although, strictly speaking, not part of the origin of replication but often located nearby, elements on some plasmids specify a stability function known as a *partition locus*. The exploitation of naturally occurring partition systems that maintain copy number and select against plasmid loss has been a successful approach to plasmid maintenance in long-term cultures. An example is the incorporation of the *parB* locus on vectors. This locus selects strongly against plasmid loss by killing the daughter cells that no longer carry the

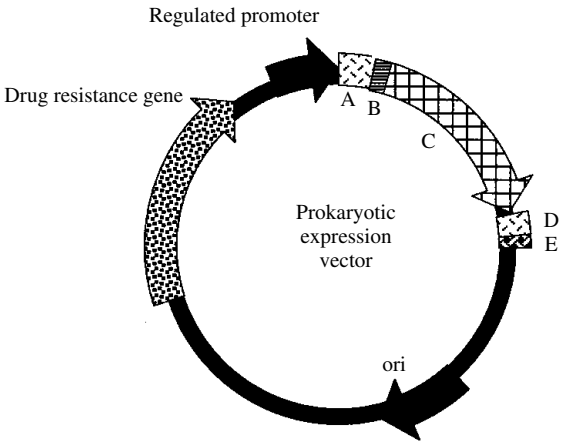

Fig. 1 A typical prokaryotic expression plasmid.

A = strong translation initiation signal
B = restriction sites for cloning
C = coding region of protein of interest
D = translation termination signal
E = strong transcription terminator
ori = origin of replication active in bacterial host

parB locus. This system does not require any specially constructed host strain.

2.2 Selectable Markers

The ability to select the vector and maintain the plasmid in the host cell is an important aspect of the expression system, especially in production regimens that involve a longer time course or continuous culture fermentations. The most common type of selectable marker incorporated on the plasmid is an antibiotic resistance element that allows selection with ampicillin, kanamycin, or tetracycline. Metabolic markers can also be used, for example, those allowing the cell to grow on a certain carbon source (e.g. sucrose) or those allowing the cell to grow without addition of an amino acid if the host usually requires it (e.g. a tryptophan requiring cell and a tryptophan marker).

Other approaches place an essential gene on the vector and use a special host strain in which that gene is deleted from the chromosome (e.g. the valine tRNA synthetase *valS* or the single-stranded DNA-binding protein *ssb*). If the plasmid is lost from the cell, the host cell alone is unable to grow. In such a system, addition of an antibiotic is not needed to select for the plasmid. This type of selection strategy is advantageous in reducing the cost of the media for large-scale production.

2.3 Transcription and Translation Signals

The transcription and translation signals allow the coding region of the gene to be efficiently recognized by the host cell machinery (i.e. RNA polymerase and ribosomes) that decodes the nucleotide sequence of the DNA of the gene into the appropriate sequence of amino acids in the protein. The signal specifying where

transcription starts is called the *promoter*. The more efficient the promoter, the greater the synthesis of messenger RNA of the gene under its control. Certain expression vectors employ a relatively strong promoter that is unregulated and is called a constitutive promoter. This approach is feasible if the protein to be made is very stable in the cell and does not cause any toxic effects or retard growth. More generally, however, a regulated promoter that can allow production of the desired protein at a suitable time in the production culture is used. This approach has two advantages: a short period of protein synthesis, and induction during the growth of the batch culture at the most opportune time (i.e. the period during which the optimal combination of cell density and specific protein production can be achieved).

The most widely used control systems for transcription initiation are those regulated by temperature or by the addition of a chemical agent or metabolite. A strong promoter from the bacteriophage lambda is normally prevented from binding to RNA polymerase by a repressor. If an altered form of the repressor is used, which is unstable at high temperature, an increase in temperature will release this negative control of the promoter, allowing large quantities of the desired messenger RNA to be synthesized. This promoter system can also be released from the control of the repressor by addition of DNA-damaging agents. This method is sometimes used instead of an increase in temperature.

Another widely used system is based on the repressor control of the lactose promoter. The DNA sequence bound by the lactose repressor can be combined with a variety of other stronger promoters (e.g. the tryptophan operon or lipoprotein gene promoters) by introducing the repressor binding site next to the promoter. In the new hybrid, the binding of the lac repressor blocks transcription, and the modified promoter then becomes controlled by the lactose repressor. The addition of an analogue of lactose, isopropylthiogalactoside, is most commonly used to induce the system.

A number of other regulation systems have been advocated for process control. Among these are phosphate, oxygen, acid, and arabinose. Each of these controlled systems can yield high expression under induced conditions, and particular conditions have been developed for each. Some are more appropriate for controlled levels of induction in smaller-scale laboratory experiments, and some have been specifically developed with the economics of large-scale culture in mind (e.g. oxygen). Some examples of regulatable promoters can incorporate a measure of feedback control into the host–vector circuit to balance expression to suit metabolic purposes. More elaborate combinations of regulatory genes controlled by different promoters can give rise to special responses or especially tight control of expression.

Some promoters are regulated by specific activators that stimulate transcription rather than by a negatively acting repressor system. An extension of the idea of regulating transcription initiation is the production of the desired messenger RNA through the use of a special RNA polymerase, not normally found in the cell, in combination with its unique promoter sequence. A system based on the bacteriophage T7 RNA polymerase and the T7 promoter it recognizes can yield very high specific production of the desired product. In this case, the T7 promoter would be located on the expression vector, and the T7 RNA polymerase gene is usually located on the chromosome under the control of a regulated system,

typically of the type just mentioned. Thus, induction in this system (e.g. by isopropylthiogalactoside addition to induce the lac repressor–controlled promoter) first produces the T7 RNA polymerase, which in turn synthesizes the specific messenger RNA corresponding to the gene of interest. Many variations of the T7 promoter expression system have been made and are commercially available.

Once a suitable means of producing the messenger RNA encoding the protein of interest has been defined, the next consideration is to translate the messenger RNA with optimal efficiency. Several factors affect this efficiency. One is the stability of the message. If the messenger RNA has a longer half-life in the cell, it can be translated proportionally more often before it is degraded. The presence of hairpin secondary structures, in which the nucleotide sequence allows intramolecular base pairing, particularly near the end of the message, seems to help stabilize the messenger RNA from degradation. Hairpin sequences act as part of the transcription termination signal and are normally included in the vector construct at the 3′ end of the message beyond the protein-coding sequence.

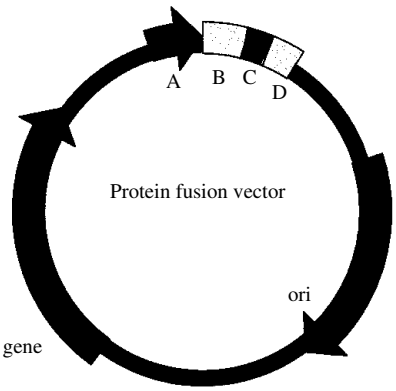
The major factor usually limiting translation is the ability of the ribosome to initiate translation on the messenger RNA. The ability of the ribosome to bind effectively to the messenger RNA can be impeded by secondary structures in the message, which block access to the translation initiation codon. The binding of the ribosome to the messenger RNA requires interaction between the ribosome, specifically including a segment of the ribosomal RNA, and the region of the messenger RNA about 10 nucleotides 5′ from the translation initiation codon. Optimal sequences for this ribosome binding region have been analyzed for a number of genes, and sequences corresponding to a highly efficient ribosome binding site are often included in the vector just preceding the position at which the protein-coding sequence is to be placed. Nucleotide sequences frequently placed in vectors for their efficient ribosome sites include chemically synthesized optimal consensus sequences, the T7 g10-L region, or those of other highly translated genes. While these standard translation initiation systems are suitable for adequate expression of most proteins, the sequence in this area often needs to be optimized to gain the highest level of production of a specific protein. Translational limitations can also occur as a result of the specific nature of the protein-coding region (e.g. unusual base composition, unique codon usage, or special secondary structures). These problems cannot be addressed at the expression vector level but sometimes can be addressed by selection of the host strain or by being optimized individually for that specific gene.

2.4 Restriction Sites for Cloning

Careful selection of the location of the restriction endonuclease cleavage site at which the protein-coding sequence is to be introduced into the plasmid can allow the expression of the protein in its most useful form. In many cases, it is desired to produce the complete intact natural protein, beginning with its N-terminal amino acid and ending with the native C-terminal amino acid. This is frequently the case when the exact structure of a mature, natural, pharmaceutically active protein is needed. To position the coding sequence correctly with respect to the ribosome binding site, a specific restriction endonuclease site incorporating an ATG

sequence can be used to place the translation initiation codon specifying methionine appropriately in the vector. Two commonly used restriction enzyme sites that contain an ATG and rarely exist in any given DNA sequence are *Nco* I and *Nde* I. A second unique restriction site is often used at which the C-terminal end of the gene is joined to the vector to orient the protein-coding segment during cloning. Such a construct would then enable translation of the complete cloned protein-coding region.

Although not all mature proteins have an N-terminal methionine, this is the primary product formed in bacterial systems. An extra N-terminal amino acid can be removed from the protein after synthesis by *in vitro* methods, or the desired protein can initially be made as part of a longer peptide chain with subsequent cleavage by a specific protease to generate the N-terminus of the mature protein product. A variety of N-terminal protein carrier elements have been used to make protein-fusion products (Fig. 2). In the formation of a fusion protein, the vector carries the appropriate signals for translation initiation as well as a coding region of the N-terminal component of the protein and a restriction endonuclease cleavage site at which the DNA fragment bearing the foreign gene can be placed in the proper reading frame. The properties of the N-terminal component of the protein fusion can be used to assist in purification of the fusion protein. For example, if this segment encodes an easily purified protein such as the maltose-binding protein or glutathione *S*-transferase, the combined fusion product can be readily isolated using affinity chromatography, which takes advantage of the binding properties of the attached protein component. The addition of traces of basic, acidic, or metal-binding amino acids (his-tag) in the carrier protein can also be used to aid in purification. This protein fusion concept can be utilized to allow for protein processing *in vivo*. For example, if the N-terminal segment encodes a localization signal, the protein can be directed to the periplasmic space of *E. coli* or, in some



A = promoter
B = fusion tag for N-terminal fusion (e.g. glutathione *S*-transferase or oligohistidine tag)

ori = origin of replication

Fig. 2 A typical protein fusion vector.

cases, into the extracellular medium. This type of export can aid in the purification and stabilization of the protein. A vector employing protein A as the carrier portion is one of this type. C-terminal fusions can also be made where the added protein function is located at the 3′ end of the gene-coding sequence. There are also fusion-protein modules that can form a protease and cleave themselves out of the fusion protein to generate the proper linear protein product.

In some applications, the expression of the entire protein is not necessary. For raising antibodies or for the detection of an antigen by antibodies, only a short recognizable epitope is necessary; so in these cases, expression of only a short protein segment is sufficient. The cloned segment comprising the antigenic site or functional domain can be attached to a protein carrier segment that will allow effective exposure or activity of the foreign peptide. Placement of the foreign segment at the C-terminal end of the carrier protein has been used effectively for this purpose. In some cases, a suitable cell-surface protein can be used as the carrier portion to ensure that the foreign protein segment is localized to the surface of a cell or bacteriophage particle (phage display), thus presenting an immunologically active antigen or antibody species in a way that allows detection, isolation, or use of the living cell or virus particle. Such constructs are very useful for identifying protein segments that effectively bind specific molecules.

3 Choice of Expression System

Even considering the limited area of expression systems for *E. coli*, there is a wide choice of expression host–vector combinations. The system that is generally appropriate for a particular use is mentioned here. A few examples of specialized uses include the use of lambda vectors for ease in screening for expressed antigens in recombinant clones, phage-display vectors to look for specific epitopes or binding peptides, and vectors with simplified cloning systems for high-throughput analyses of many ORFs from genomic sequences. Specialized systems for examining protein–protein interactions in yeast or bacteria have been developed to identify protein domains that can bind to each other in functional complexes *in vivo*. *In vitro* expression systems can also be used, and these systems have improved and are available commercially to enable expression of protein from DNA in a small scale suitable for screening of a desired property of the protein if a suitably sensitive assay is available.

Families of related vectors are also available, which use a simplified recombination system to transfer the expressed gene among a variety of vectors suitable for different hosts or applications. This modular approach can allow a variety of hosts to be examined for protein production or to test the biological properties of the protein in different cells. These systems offered by various suppliers allow versatility in subsequent expression experiments without separate recloning steps.

3.1 *Escherichia coli*

The use of the correct host can have a significant impact on the final yield and quality of the desired protein product. In addition to the special genetic features that may be required for functioning of the plasmid vector system, there are other host features that are of general

importance. Factors generally useful for the host include the ability to grow rapidly and to a high density, the ability to be transformed in a manner that facilitates the introduction of the DNA construct, and the possession of a low recombination and mutagenic rate to ensure that the plasmid is not frequently lost, damaged, or otherwise inactivated. Stability to degradation is a major problem in the production of certain proteins. Therefore, host cells with reduced protease levels have been used to enhance the *in vivo* stability of the foreign protein of interest. Commonly used mutations in *E. coli* that have reduced protein degradation rates because of the inactivation of proteases are *lon, rpoH,* and *clp*. In some cases, the protein stability can be addressed at the expression vector level by using a fusion-protein construct. The presence of the longer carrier protein often will effectively stabilize a small foreign peptide segment. Other fusions (Nus) can be used to help solubilize the protein. Translation of large proteins may also be a limitation in many strains, but certain large proteins (e.g. polyketide synthases) have been produced in *E. coli*. The formation of insoluble inclusion bodies that contain an inactive form of the overexpressed protein has been a problem for some proteins. Strains with increased levels of chaperone proteins to help stabilize foreign proteins have been employed to attenuate these problems. Other efforts have included the use of thioredoxin, a redox protein, to improve proper folding of the protein via its use as a protein-fusion component.

3.2 Other Hosts

While *E. coli* continues to be the most widespread expression system, other host–vector systems have certain advantages. The strengths of the *E. coli* system are the variety of vectors and specifically altered hosts available, and the well-studied methods for genetically manipulating this organism. High levels of production can be attained. However, protease problems, formation of inactive inclusion bodies containing the product, and the lack of a eukaryotic glycosylation system limit production of a number of proteins from mammalian sources. Other bacteria have received some attention owing to their ability to grow on particular compounds, their potential for secretion of the protein, or their industrial potential.

Yeasts are a suitable production system for a number of processes. Not only are they well studied like *E. coli*, and amenable to scale-up, but also they are able to carry out some posttranslational processing of eukaryotic proteins such as specific cleavage or modification. Certain organisms used in the food industry are generally regarded as safe, and so less stringently purified material from such sources can be used in products for human consumption.

Several fungi are used to produce high yields of commercial proteins and are reasonably capable of glycosylation and secretion of proteins into the medium. Methods have not been so completely developed, however, and organisms of this class have not yet been as widely applied.

Viruses that infect insect cells (baculoviruses) have gained attention as a system for producing glycosylated proteins at reasonably high levels, but at less expense than is incurred using mammalian cells. While studies of the modification of proteins in various systems and the engineering of these posttranslational processing steps have made progress, this is still an area where significant improvement

can be made. The vaccinia virus has been used to express foreign antigens in whole animals, demonstrating its potential for use as a vaccine vector system. Although mammalian cell lines have been studied extensively and have the advantage of producing a truly identical processed mammalian protein, the costly, difficult scale-up acts as a limitation for commercial production with this system.

Finally, transgenic plants or animals can be used for protein production, and since the development time is long for these systems, they are suited for situations where long-term bulk production of a specific well-characterized product is warranted.

3.2.1 *Bacillus subtilis*

Bacillus subtilis has been considered to be a suitable host on the basis of several potentially advantageous properties. Considerable information is available concerning its molecular biology, physiology, and genetics. The details of translation, transcription, and plasmid systems are well studied. The employment of *B. subtilis* and related *Bacillus* species in other industrial production situations also has stimulated the development of *B. subtilis* for the production of recombinant proteins. Perhaps the most commercially interesting reason for using *B. subtilis* is the ability of this microorganism to secrete proteins into the medium. A simple system that would allow isolation of the protein from the supernatant broth directly, without the requirement for cell disruption, would simplify the downstream processing portion of the production process.

The expectation that *B. subtilis* would play a major role in the commercial production of recombinant proteins has been unrealized largely as a result of technical factors. Although regulated expression systems are available for *B. subtilis*, and secretion systems based on α-amylase, alkaline protease, or levansucrase have been reported, their use has been limited. The secretion system can be made to release some heterologous proteins into the medium, but not all of them are processed well. Another problem has been the presence of proteases that act to degrade the desired protein. This difficulty has been approached through the development of strains in which genes for several of the proteases are inactivated. Early observation of plasmid instability led to the development of integrated expression systems, in which the promoter and the gene to be expressed were recombined onto the bacterial chromosome. This strategy takes advantage of the active recombination system of *B. subtilis* to integrate the construct and thereby stabilize it. This approach to the formation of a stable overproducing strain may become more generally used in other organisms.

3.2.2 Yeast

Yeasts have many of the advantages of bacteria, for example, they are fast growing, high cell density is achieved, industrial-scale processes are established, and molecular biology and genetics are well developed; however, as eukaryotes they are capable of more sophisticated posttranslational protein processing than that found in bacteria. Yeasts have the transcription regulatory features and processing system of a eukaryotic cell. A general diagram of eukaryotic signals found in many expression vectors is presented in Fig. 3. The most commonly used yeast in laboratory research is *Saccharomyces cerevisiae*, an organism that can be cultured in the haploid state. Most industrial strains, however, have more than one copy of each chromosome per cell, which makes them more difficult to manipulate genetically.

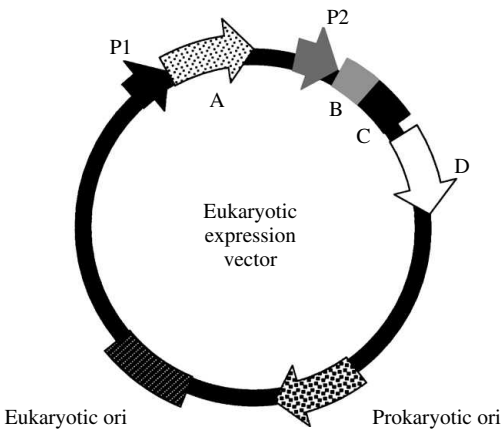

Fig. 3 A typical eukaryotic expression vector.

P1 = prokaryotic promoter
A = drug resistance for selection in prokaryotic systems
P2 = eukaryotic promoter
B = restriction sites for cloning
C = poly A feature
D = drug resistance element with expression features for selection in eukaryotic systems

Other yeasts, such as *Pichia pastoris* and *Hansenula polymorpha*, have also been investigated and may offer an advantage in the production of glycosylated proteins. *S. cerevisiae* vectors of either the plasmid or integrating type are available. The most common plasmid-based system derives from the 2 µm plasmid found in the nuclei at about 60 to 100 copies per cell. A large number of vectors have been derived from this plasmid, with the copy number varying depending on the size of the insert, the selective marker, and the growth conditions. Vectors employing promoters affected by the carbon source have been used to give high-level expression of heterologous proteins. Examples include various GAL4-regulated promoters, the alcohol dehydrogenase ADH2 promoter, the phosphoglycerate kinase promoter, the glyceraldehyde 3-phosphate dehydrogenase promoter, and temperature-regulated or copper-regulated systems.

The secretion and glycosylation abilities of yeast have received attention. The α-mating-factor secretion signal has been one of the most used, with the desired protein-coding sequence placed just after the α-factor segment specifying the signal for secretion and cleavage by protease. Yeast is capable of glycosylation, but the addition of sugar modifications to expressed human proteins is somewhat different from that found in the natural protein. For example, the protein produced in yeast often bears additional sugar residues at asparagine glycosylation sites. To reduce overglycosylation, *mnn* (mannan defective) or *alg* (asparagine-linked glycosylation) mutants of yeast have been studied and used as hosts for protein production. In efforts to improve the stability of proteins degraded by the vacuole proteinases, mutations that disrupt these protease genes have been introduced. The use of these special yeast strains has enhanced the ability

to isolate a number of proteins. Studies of the ubiquitin-mediated protein degradation process and the N-terminus removal or acetylation systems have led to the use of special strains or growth conditions to allow the desired N-terminus on the mature protein to be obtained. A major use of the yeast two-hybrid system for identifying interacting protein domains in functional genomics has been found, which can help elucidate possible functions for unknown proteins.

3.2.3 Mammalian Cells

Expression of proteins in mammalian systems affords production of the identical animal protein and thus eliminates any question regarding the effectiveness or natural character of the protein. Such factors as the expense of mammalian cell culture, low cell density, and low productivity have limited the use of this system to investigations in which the synthesis, processing, or role of the protein is being explored, or the protein cannot be satisfactorily expressed in a more amenable system.

While COS monkey cells are often used in combination with viral vectors for transient expression purposes for research experiments (Fig. 4), the development of a cell line capable of sustained production in a serum-free suspension culture is desired for long-term production. Suitable lines have been established in COS, CHO, mouse L cells, or other lines by linking the expression construct for the desired gene to a readily selected marker and integrating the entire DNA into a random chromosomal location (Fig. 5).

The expression construct usually contains an enhancer element, which allows the production of high-level expression (e.g. SV40, polyoma, or adenovirus enhancers; the heavy-metal-responsive metallothionein enhancer; glucocorticoid-responsive enhancers). An active promoter (e.g. the SV40 early promoter, the Rous sarcoma virus (RSV) promoter, adenovirus major late promoter) is commonly used, and appropriate efficient splicing

3′ LTR = long terminal repeat sequence which enables recombination for stable expression
E = drug resistance gene for selection in bacterial cells

signals derived from SV40, adenovirus, or immunoglobulin genes are also positioned on the expression vector along with polyadenylation signals.

To select for the presence of the integrated construct in the recipient cell line, a readily selectable gene is linked to the expression construct. A selectable marker that is frequently used is that specified by dihydrofolate reductase, which allows the cells to grow in the presence of methotrexate. Other selectable genes that can be used in a similar way are those for adenosine deaminase, ornithine decarboxylase, or asparagine synthetase, although in some cases a specific mutant cell line is required for selection. After the construct has been introduced into the appropriate cell line by calcium phosphate, DEAE-dextran, liposome-mediated transfection, or electroporation, the cells are grown under selection and with increasing levels of the selecting agent (e.g. methotrexate for dihydrofolate reductase gene amplification), and the genomic region at which the construct is integrated becomes amplified. This amplification provides a high gene dose in the genome of the host cell and increases the level of synthesis of the protein ten- to several hundredfold. Once formed, such cell lines can be stably maintained if care is taken to monitor for deletions. Improvements in the production level attained by single-copy integrated vectors and their adaptation to growth in serum-free suspension culture have simplified the use and prospects for mammalian cell production without modification.

For expression of a mutant form of a protein in a mammalian host, there are methods for homologous recombination, and these can be used to analyze the role of the protein in cell physiology.

3.2.4 Insect Virus

Insect virus expression systems for the production of proteins, particularly glycosylated mammalian proteins, have received attention because of the high level of expression (up to 50% of total cell protein) available with this technology. The baculovirus system employs strong transcription signals for expressing the polyhedron protein of the virus. These viruses replicate in the nucleus and form inclusion bodies, which are surrounded by a protective matrix containing a large amount of the polyhedron protein. The virus commonly used is *Autographa californica* nuclear polyhedrosis virus, and it is cultured on the cells of the fall armyworm, *Spodoperta frugiperda*. Silkworms can also be used as the host, providing a simple, low cost route for production.

This virus is so large (130 kb) that direct manipulation of the viral DNA is difficult, and the desired gene is usually introduced through *in vivo* recombination between the foreign gene construct and the viral genome. Newer methods for making the recombinant baculovirus at higher efficiency by incorporating a positive selection for the recombinants coupled with the introduction of reporter or detection systems have simplified the task of generating and identifying the desired viral expression constructs. Insect viruses have also been shown to infect a number of other cell types in the laboratory.

3.2.5 Vaccinia Virus

Vaccinia virus vectors have been used in the preparation of vaccines for animal diseases. The virus is a large poxvirus, which replicates in the cytoplasm of the host cell. While the virus is not a health hazard to humans, it is quite immunogenic and thus serves as a suitable carrier for the antigenic surface proteins of other viruses. The recombinant vaccinia virus is prepared by recombination *in vivo*, as is the case for the baculovirus system. A variety of markers are available for identification or selection of the recombinant viruses. These include β-galactosidase, thymidine kinase, neomycin resistance, and mycophenolic acid resistance. The introduced gene is placed under the control of a vaccinia virus promoter with appropriate signals, as in the case for expression in mammalian cells, and the host cells (e.g. CV-l cells) are coinfected with the vaccinia virus and the above-described construct bearing the desired gene, the expression signals, and the selective marker. After characterization, the recombinant vaccinia virus can be propagated on any suitable host. The antigenic components of several important disease-causing agents have been placed on the virus in this way (e.g. hepatitis B; rabies and herpes viruses). The recombinant vaccinia viruses seem to be able to produce an effective immune response to the foreign protein in whole animals.

3.2.6 Transgenic Plants and Animals

Whole plants or animals have been used as production systems. This strategy entails the preparation of the expression construct as for expression in mammalian cells and then introducing it into a cell that can be reproductively transmitted in a whole organism rather than into cultured cells. The integration event allows the altered chromosomal segment to exist in germ line cells. In this situation, the construct can then be transmitted to all the cells of the progeny of the original transgenic animal and on through succeeding generations.

The most widely used system for the production of a specific protein from transgenic animals takes advantage of the large amount of concentrated protein

secreted into milk by the mammary gland. The desired gene is attached to the synthesis and secretion signals used for natural production of the abundant milk protein, casein. This approach has been taken with sheep, goats, or cows, which are then able to secrete human interferon, α1-antitrypsin, or human factor IX in their milk. High levels of the protein can be produced (e.g. >10 g L^{-1} per liter of milk in some animals). The strategy enables long-term production and facilitates isolation of the protein in quantity without harming the animal. Once prepared and characterized, a herd of such animals would have a very low continuing production cost.

Transgenic plants can be created by the introduction of genes via infection by *Agrobacterium tumefaciens*, a bacterium that can pass the DNA of its Ti plasmid into plant cells, where this segment integrates into the plant genome. In nature, this transformation of plants by the bacterium generates a gall or tumorous callus on the plant at the site of the wound at which the infection occurred. By genetically engineering the Ti plasmid to remove the tumor-causing genes while retaining the DNA-transfer capability, useful vectors have been prepared. To effectively express a gene in the plant, suitable transcription and translation signals need to be incorporated surrounding the gene. Signals that have been used for this purpose are the nopaline synthetase promoter, the promoter from the gene for the small subunit of the carbon dioxide–fixing enzyme, ribulose bisphosphate carboxylase, and those derived from the cauliflower mosaic virus. In some instances, the gene can be expressed in specific locations in the plant where the metabolic consequences of the protein may be most desired.

The generation of a transgenic plant calls for the use of cells that are susceptible to infection and are competent in regenerating a plant through culturing techniques. These two criteria have limited the system for some plants. *Agrobacterium tumefaciens* infects dicotyledonous plants, a group that does not include most cereal plants. For the cereals and many other plants, DNA can be introduced into the cells by coating it onto an inert projectile and firing it into plant leaves or embryogenic calluses. Recombination followed by propagation from single cells under appropriate selection (usually kanamycin or phosphinothricin) can generate the transgenic plant. Fertile transgenic rice, corn, soybean and wheat plants have been formed. So far, the genes introduced into plants have been mainly intended to increase resistance to herbicides, insects, or viruses, and these are in wide commercial use (e.g. corn and cotton). Such properties as ripening, taste, or nutritional characteristics can also be altered.

The expression of industrially useful proteins in bulk in the seeds of plants has also been possible. This could have advantages for large-scale production of stable proteins and has been proposed as a method for generating antigens suitable as vaccines.

Viral vectors can also be used with certain plant species (e.g. cowpea mosaic virus), and they have been used to express animal virus surface antigens in whole plants. This approach is attractive in that the virus is easily isolated and stored and is very immunogenic but cannot harmfully infect animals.

4 Process Considerations

The synthesis of protein from cloned genes relies solely on the metabolic machinery

of the host cell. Consequently, any process factors that affect the host cell physiology will have a significant impact on the ultimate expression level. Factors such as temperature, impeller agitation speed, and medium formulation or feeding strategy in the case of a fed-batch fermentation are important variables to be considered in arriving at a production process. In industrial processes, where high volumetric productivity is the desired goal, extensive optimization studies are performed with these variables to achieve maximal overproduction of the specific protein in the shortest practical time.

Several general themes from the vast experimental observations of process conditions on *E. coli* protein production are mentioned here. The composition of the growth medium can affect both cell growth and recombinant protein yield. A complex medium generally yields a higher productivity. This is due to the presence of biosynthetic intermediates and cofactors, which the cell does not then need to synthesize, thus decreasing the metabolic burden. A balanced carbon-to-nitrogen ratio in the medium is also critical in achieving a high yield of recombinant protein. The temperature has a significant effect on cell growth and the waste products accumulated. The formation of acetate, a harmful waste product, is increased at high temperature. Lower temperature generally favors the formation of soluble protein, while higher temperature encourages the accumulation of the protein in inclusion bodies.

Another challenging task is to provide an adequate supply of oxygen to the culture, especially for dense cultures. The transfer of oxygen from the air stream can be increased, to a certain extent, by increasing the agitation speed. Oxygen supplementation is required in some cases, and genetic manipulation of the host by introduction of an oxygen-binding protein has also given positive results.

Waste product accumulation has a detrimental effect on recombinant protein production. Strategies to limit the effects of waste products have included lowering the temperature of the culture, carefully controlling the nutrient supply in a fed-batch system, and the use of genetically altered hosts that exhibit reduced levels of harmful metabolic products.

5 Perspectives

The ability to clone and express high levels of specific proteins in other organisms has led to great advances in the speed and detail with which biological systems can be analyzed. With the expansion of this technology to other organisms and the construction of more complicated and sophisticated derivatives of currently studied systems, the impact of this area will increase. Recombinant protein production has now become widely applicable with industrial microorganisms, the formation and use of transgenic plants and animals, and the analysis of unknown proteins associated with genetic disorders. The area of proteomics and the efforts to decipher the function of the coding regions of sequenced genomes will lead to an even greater use of expression systems and the development of more efficient specialized systems.

Primary Literature 411

Keywords

Betaglycan
A membrane, proteoglycan, originally discovered to be an accessory receptor for TGF-β2 (hence, also called TGF-β type III receptor), but now shown to bind inhibin with high affinity in a complex with activin type II receptor, thereby antagonizing activin actions.

BMPs
Bone morphogenetic proteins are bone-growth regulatory factors that belong to the TGF-β superfamily. They are synthesized as large precursor molecules, that are cleaved by proteolytic enzymes. The active form can consist of a dimer of two identical proteins or a heterodimer of two related bone morphogenetic proteins.

Endocrine Regulation
Regulation by a hormone made by an organ and secreted into the bloodstream, where it circulates and influences specific target organs.

Endothelins
Peptides of 21 amino acids with potent vasoconstrictor as well as mitogenic and hormone-releasing properties, made by a variety of epithelial and vascular smooth muscle cells.

Folliculogenesis
A developmental process in which follicles undergo a coordinated progression of recruitment, development (or atresia), selection, and ovulation.

FSH Isoforms
Forms of follicle-stimulating hormone that differ in the degree of glycosylation of the mature protein leading to differences in their biochemical properties and circulating half-lives in the blood.

G-Proteins
Coupling proteins, so-called because they bind GTP, which link receptors to effector molecules. They regulate a variety of enzymes and ion channels. The G-proteins form a heterotrimeric complex of α, β, and γ subunits. There are multiple members of each family of subunits, giving rise to a complexity of responses.

Gonadotropin-releasing Hormone
A decapeptide synthesized in hypothalamic neurones; it is released in a pulsatile fashion into the hypothalamic–pituitary portal blood system, and stimulates synthesis and release of gonadotropins by the pituitary gland.

Gonadotropins
Glycoprotein hormones, called *follicle-stimulating hormone*, *luteinizing hormone*, and *chorionic gonadotropin*, consisting of a common α subunit linked to a hormone-specific β subunit, which stimulate ovarian and placental cells.

GDF
Growth and differentiation factor, originally discovered in a search for extracellular factors essential for mammalian embryonic development. There are now numerous family members, some of which are also called BMPs due to their sequence homologies.

IGF
Originally called somatomedins, these are insulin-like polypeptides made by the liver and released into the blood when stimulated by somatotropin. Now known as insulin-like growth factors, of which there are IGF-I and IGF-II, they cause sulfate incorporation into collagen, RNA, and DNA synthesis, and are important for cell growth and differentiation.

IGFBP
A family of six of soluble proteins (termed IGFBP-1 through to -6) that bind insulin-like growth factors and modulate their biological actions at the cellular level.

Leukemia Inhibitory Factor
A pluripotent cytokine that inhibits differentiation of embryonic stem cells, is expressed in endometrial epithelial cells, and has been shown to be essential for implantation in mice.

Local Regulation
Autocrine or paracrine regulation of cells by factors made locally within a tissue.

Oxytocin
A nonapeptide with uterotonic, prostaglandin-releasing, and milk-letdown activities, made by hypothalamic neurones and ovarian cells.

Receptors
Membrane or intracellular polypeptides that bind hormones or other factors with a high degree of specificity and transduce the signal to the cell either as transcription factors regulating genes or via a second-messenger system.

Second-messenger Systems
Small cytoplasmic molecules, which, when activated, amplify the signal they receive (e.g. cyclic AMP and inositol phosphate).

Signal Transduction
The process by which a signal received at the cell surface is passed from one carrier to another to achieve a cellular response.

Steroidogenic Enzymes
A family of enzymes, many of which belong to the P450 gene family, that catalyze the synthesis and metabolism of steroid hormones such as estrogens, progestogens, and androgens.

Tissue Remodeling Enzymes
Enzymes belonging particularly to the matrix metalloproteinase family, such as MMPs 1, 2, 3, 7, and 9, and their associated tissue inhibitors, the TIMPS, which are responsible for remodeling the constituents of basement membranes and the extracellular matrix during growth, angiogenesis, tissue breakdown, and wound healing.

Transforming Growth Factor β-Superfamily
A family of pleiotropic factors that have high homology at the level of the gene and in their tertiary protein structure. Examples include TGF-β, inhibins, activins, and Müllerian-inhibiting substance.

Transmembrane Helices
G-protein-linked receptors are a family of receptors characterized by a structural motif of seven hydrophobic regions that span the cell membrane, forming a helical structure within the membrane.

Zona Pellucida Proteins
A family of highly glycosylated proteins unique to the surface coat of the oocyte, several of which serve as primary and secondary sperm binding proteins on the egg at the time of fertilization.

The female reproductive system consists of the hypothalamus, pituitary, ovaries, breasts, and uterus. These organs make up a finely tuned system that controls puberty, the menstrual cycle, pregnancy and birth, lactation, and menopause. With the tools available through molecular biological approaches, we are able to come to a greater understanding of the complex interactions that operate in this system. The hormones, growth factors, and enzymes that are able to exert unique and specific effects in this system do so either locally or via endocrine mechanisms. The elucidation of the molecules involved in this regulation and their mechanisms of action leads to a better understanding of the physiology and pathophysiology of reproduction, and provides the potential means for developing better methods to control fertility and infertility.

Outlined below are some of the major hormonal regulatory systems that are important in the female reproductive processes.

1
Principles: Regulation of Reproductive Processes in the Female

1.1
The Hypothalamic-pituitary-ovarian-uterine Axis

The regulation and coordination of all facets of the reproductive process in the female are controlled by the hypothalamic–pituitary–ovarian–uterine axis (Fig. 1). The activities of numerous hormones, growth factors, and cytokines, and their receptors and binding proteins, as well as enzymes, structural proteins, and other factors within this axis control the development of the reproductive system in fetal life and during puberty, as well as the cyclic production of hormones and eggs during reproductive life, the establishment and maintenance of pregnancy, the birth process, lactation, menopause, and the secondary sex characteristics.

An important process in female reproduction is ovarian folliculogenesis. This is a complex and dynamic process in which the follicles undergo a coordinated progression of recruitment, development or atresia, selection, and finally ovulation (Fig. 2). Peripheral endocrine hormones and local paracrine and autocrine factors contribute to this process.

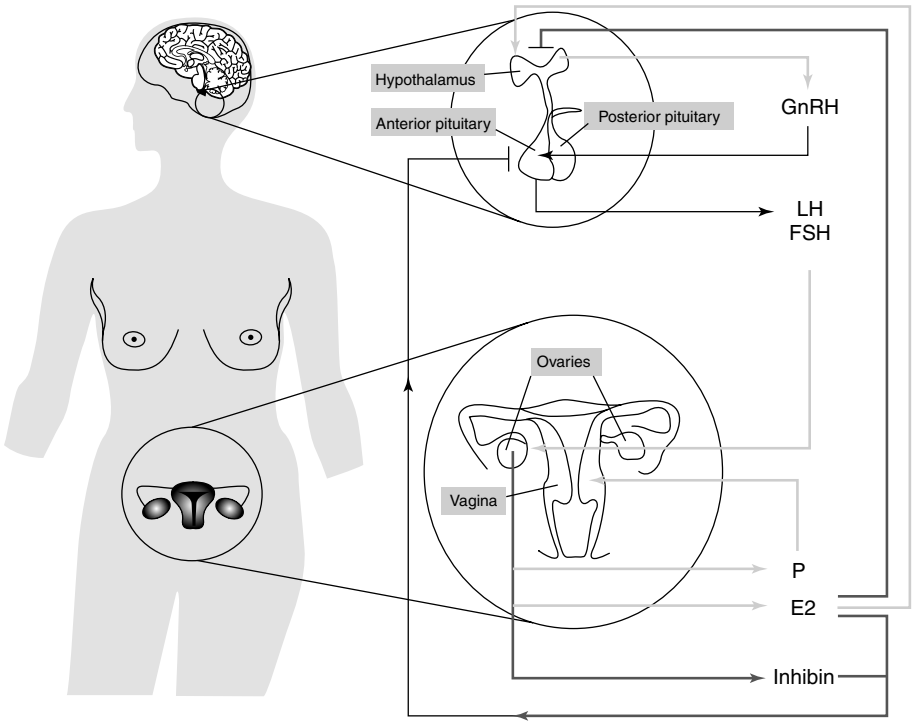

Fig. 1 Hormonal feedback control of the hypothalamic–pituitary–ovarian–uterine axis. Positive feedback is indicated by the blue lines, negative feedback by the red lines, and arrows indicate the direction of the controlling pathways. Estrogen has both positive and negative control on the hypothalamus, depending on the stages of follicular development. (See color plate p. xxi.)

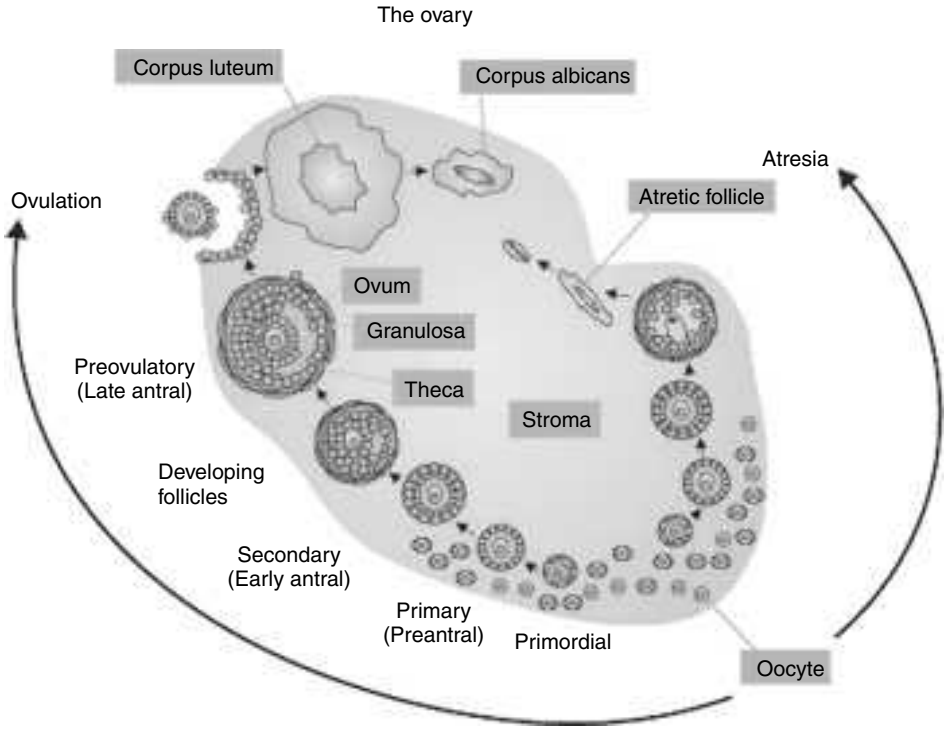

Fig. 2 Schematic representation of folliculogenesis. Follicles can be quiescent (i.e. primordial), committed to growth (preantral and antral), ovulatory, or atretic. Follicles are believed to leave the primordial pool in an ordered sequence, but at an unknown rate and become irreversibly committed to growth. The mechanisms responsible for the reinitiation of growth of primordial follicles remain unknown.

1.2 Levels of Regulation

The hypothalamic–pituitary–gonadal axis was characterized originally by the positive and negative feedback relationships of the endocrine hormones that had been shown to regulate the reproductive system (Fig. 1). For example, gonadotropin-releasing hormone (GnRH) released by the hypothalamus into the hypophyseal portal circulation stimulates both the synthesis and secretion of the luteinizing hormone (LH) and the follicle-stimulating hormone (FSH) by the gonadotropes in the anterior pituitary. FSH then stimulates production of estradiol-17β (E2) by the ovarian follicle; E2 in turn has a negative feedback effect to limit the production of FSH, and so an equilibrium is established that ultimately determines the extent of stimulation of egg and hormone production by the ovary.

In addition to the endocrine regulation of this axis, there is regulation at the organ and cellular level by locally produced growth factors and cytokines. Some of the endocrine hormones also act locally. For example, E2 is produced by the ovary and acts directly on the follicles; prostaglandins produced by the endometrium act within the uterus. The growth factors, cytokines, enzymes, and other factors identified more

recently within the reproductive axis are structurally identical to those produced in other organ systems. Nevertheless, they can be differentially regulated and can perform functions specific to the reproductive axis. Examples are the cyclic tissue remodeling by matrix metalloproteinases (MMPs) and angiogenic factors in the ovary and uterus, the role of activin in the functions of the pituitary, ovary, and placenta, and the actions of the insulin-like growth factors (IGFs) and their binding proteins in the ovary and endometrium.

1.3 Specificities of Actions

It has already been said that many of the hormones and other regulatory factors are not unique to the female reproductive system even though they perform specific functions. Regulation of hormones and cytokines occurs at their sites of production and at their sites of action by cell-specific expression of their receptors; the presence of binding proteins and metabolizing enzymes determines the extent and specificity of their actions.

The few substances that are unique to the reproductive system can generally be found in both the female and the male; they include GnRH and its receptor, FSH and its receptor, LH and its receptor, Müllerian-inhibiting substance (MIS) and its receptor, oxytocin, and relaxin. Substances unique to the female are the placental proteins such as the chorionic gonadotropins and lactogens (and a special class of interferons, ϕ, in ruminants), and the zona pellucida proteins (ZP1, 2 and 3), which coat the oocyte.

It is not possible, in the space available, to give a full account of the expression and actions of all the factors involved in regulating the female reproductive system. Therefore, we have briefly summarized selected examples of a number of hormonal regulatory systems to provide some insights into the subject. The reader is referred to the bibliography and to other references therein.

2 Examples of Regulatory Systems

2.1 The Steroidogenic System

2.1.1 Estrogen and its Receptors

Estrogens, androgens, and progestogens are the sex steroids regulating the female reproductive axis. They originate primarily from the ovary and the placenta, with important contributions by the uterus, adrenal gland, and other peripheral organs such as fat cells and skin. During the ovarian cycle and pregnancy, steroid secretion by the ovary and placenta occurs in a highly regulated and episodic fashion that is determined in part by the pituitary and placental gonadotropins. Changes in the levels and activities of the steroidogenic enzymes are major mechanisms determining these changes.

The synthesis of the steroids involves successive elimination of carbon atoms from the precursor, cholesterol, catalyzed by members of the cytochrome P450 gene family, namely, cholesterol side-chain cleavage cytochrome P450 (P450scc), 17α-hydroxylase (P450c17), and aromatase (P450arom) (Fig. 3). There are also 3α- and β-, 17α-, and 20α-hydroxysteroid oxidoreductases, which catalyze the interconversion of some of the steroids as well as isomerization reactions. Not only the cellular expression of these enzymes but also their electron donors have been extensively investigated in the female reproductive

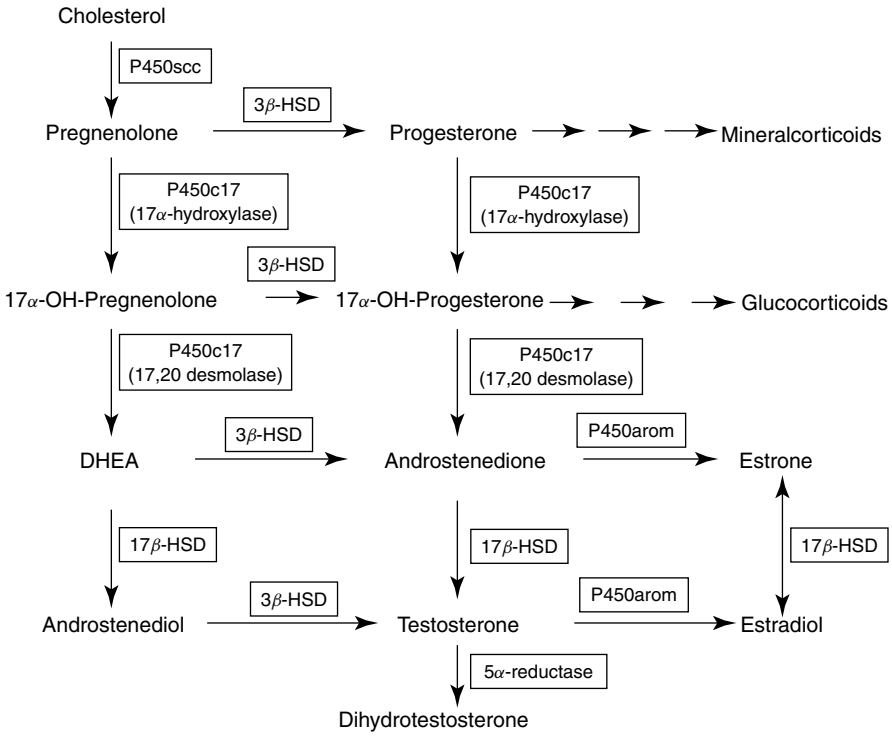

Fig. 3 Pathways involved in steroid hormone biosynthesis from cholesterol. Key enzymes involved are shown in boxes. P450c17 possesses both 17α-hydroxylase and C_{17-20} lyase (also known as 17,20 desmolase) activities. 3β-HSD is 3β-hydroxysteroid dehydrogenase, P450arom is aromatase, and 17β-HSD is also known as 17-ketoreductase.

system; studies have focused on gene expression, protein synthesis, and activity assays. The chromosomal localization of some steroidogenic enzymes is shown in Table 1.

Estrogen receptors (ERs) are ligand-inducible transcription factors. They are members of a superfamily of DNA-binding transcription factors that are divided according to their DNA-binding domains into steroid receptors, thyroid and retinoic acid receptors, and orphan receptors (lacking known ligands). The intracellular steroid receptors are generally associated with heat shock proteins, and in the presence of ligand, they dissociate from the heat shock proteins, become phosphorylated, undergo dimerization, and translocate to the nucleus.

Tab. 1 Chromosomal localization of human genes for estrogen receptors and some steroidogenic enzymes.

Components	*Chromosomal localization*
Erα	6q25.1
Erβ	14q
P450scc	15q23–24
P450c17	10q24.3
P450arom	15q21.1
5α-reductase type I	5p15
5α-reductase type II	2p23

ERs are of major importance in the female reproductive system. There are two types of ERs, called ERα and ERβ, each of which have six functional domains (Fig. 4). The N-terminal A/B domains contain the cell-specific and constitutive transactivation (TAF-1) functions and the isoform-specific sequences. The C domain or DNA-binding domain is the most conserved region, containing invariant cysteine repeats that form two ''zinc fingers,'' which are crucial for the binding of the receptor to the DNA. The constitutive nuclear localization signal is found in the C to D region, which, together with the hormone binding E domain, is the site of interaction with the heat shock proteins. The E domain is also involved in hormone binding, nuclear translocalization, hormone-dependent transactivation, and dimerization. The F domain is found only in ER. ERα and ERβ have similar affinities for estradiol-17β, but exhibit differing affinities for other natural and synthetic estrogens, which may be important for their respective roles. The two types of ERs can form homo- or heterodimers, although the ERβ form may have an inhibitory influence on the ERα in a dimer.

As would be expected from the central role and multiple actions of estrogen in the female reproductive system, ERs have been localized in cells in the hypothalamus, pituitary, ovary, mammary gland, and uterus. ERα was found to be the predominate type in the uterus and mammary gland, whereas ERβ is more abundant in the ovary. The type of cell containing ER has been found to change according to the stage of differentiation or function, and in some cases such cells can be proximal to the cells eliciting the final response. For example, in the endometrium, epithelial–mesenchymal interactions involve an action of E2 on ER on the stromal cells, which then have a paracrine influence on the epithelial cells. Expression of ER is constitutive in some cases and can be up- and downregulated by estrogen itself, and by FSH in the ovary.

The classical genomic pathway for ER signaling involves binding of the ER dimer to estrogen response elements (ERE) in the promoter region of the target gene. Binding induces a conformational change in the ER that allows interactions with coactivators, leading to transcriptional stimulation of the target gene. These genes include

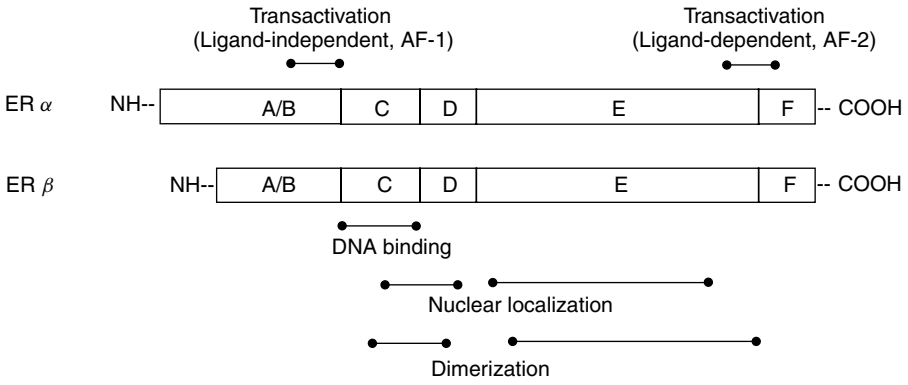

Fig. 4 The structural and functional domains of human ERα and ERβ. Structural domains are indicated as letters, and functional domains responsible for transactivation, DNA-binding, nuclear localization, and dimerization are indicated by horizontal bold lines.

some essential for reproduction such as prolactin and the progesterone receptor. ER can also alter gene transcription by a mechanism that does not involve binding of ER to the ERE. Instead, the ER interacts with other transcription factors such as Sp1, Jun, or nuclear factor kappa B, by a protein–protein interaction. Examples of genes regulated by this nonclassical pathway include collagenase and heat shock protein 27. There is evidence that this nonclassical pathway is of physiological relevance, and that it may subserve the agonist actions of selective estrogen receptor modulators or SERMs. There is also evidence for a nongenomic action of estrogen via membrane-bound receptors. This pathway is thought to mediate the fast actions of estrogen such as those associated with ion transport.

2.1.2 Roles of Estrogen in Ovarian Functions

Estrogens are essential for fertility in both males and females, but they are not necessary for survival after birth or for formation of the reproductive tract. The absence of estrogen or its actions in female rodents eventually leads to the appearance of testicular cells in the ovaries of mice with targeted disruption of the two ER genes and the *P450arom* gene. This supports a role for estrogen in somatic cell differentiation and shows that it is required for maintenance of the female somatic cell phenotype. It also underlines the plasticity of the ovary in terms of its hormonal milieu.

Estrogen has intrafollicular actions that are intimately related to the actions of FSH, the key driver of folliculogenesis. The capacity of follicles to make estrogen is limited by the thecal production of androgen, the substrate for estrogen, and the expression of P450arom in the granulosa cells, which is FSH-dependent. Although primary follicles express ER, they have little or no capacity to produce significant quantities of E2 because thecal androgen production is very low and the P450arom expression is low. FSH, together with insulin-like growth factor-1 (IGF-1) and activin, upregulates P450arom expression in the mural granulosa cells of secondary follicles. This combination of hormones, together with E2, itself stimulates proliferation and differentiation of the granulosa cells. As follicles grow, they produce more E2, the hallmark of a healthy follicle. Those tertiary or Graafian follicles selected for ovulation contain granulosa cells with the capacity to respond to LH and produce more E2.

The necessity of estrogen for normal folliculogenesis has been well established in rodent models, particularly those in which the ER and *P450arom* genes in mice have been targeted for disruption. However, it has been suggested that the ovarian roles for estrogen in polyovular species may not apply to monovular species, including women. Nevertheless, in those rare cases that document mutations in the human *P450arom* gene, folliculogenesis is not normal, and there is evidence that the follicles that are present in the ovaries are unhealthy. Further work is needed to resolve this question.

2.2 Gonadotropin System

2.2.1 Gonadotropins and their Receptors

LH and FSH are members of the glycoprotein hormone family, which also includes thyroid-stimulating hormone (TSH) and, in humans and horses, chorionic gonadotropin (CG). Each of these hormones consists of two different subunits, α and β, which are glycosylated, contain multiple disulfide linkages, and are noncovalently

linked to each other to form the active molecule. The α-subunit apoproteins are the same for all the glycoprotein hormones within a species and are encoded by a single gene comprising 4 exons, which, in the human is located on chromosome 6q12.21. The α-subunit protein contains 10 cysteines, which are involved in intrasubunit disulfide bridges and 2 N-linked glycosylation sites. The β-subunits are different for each hormone and determine the biological specificity of each hormone. The LHβ and FSHβ genes show similar genomic arrangements, suggesting a common ancestral origin. The human LHβ gene cluster is located on human chromosome 19q13.32; this cluster includes at least one LHβ gene and 6 hCGβ genes and pseudogenes. The FSHβ gene is located on human chromosome 11p13. The mature β-subunit protein contains 12 cysteine pairs that form 6 intrasubunit bridges, 2 N-linked glycosylation sites (one in LHβ) and a variable length from 111 to 145 amino acids. Addition of the carbohydrate moieties to the apoproteins is important for correct synthesis of bioactive gonadotropin dimers, and for achieving appropriate biological activity of the molecule. Regulatory mechanisms may operate through modifying the sugars on these hormones. The hCGβ protein has a C-terminal extension of 29 amino acids with 4 additional O-linked glycosylation sites that increases the half-life and biopotency of hCG over LH. It is of interest that the crystal structure of both gonadotropin subunits reveals the cystine knot structure, also seen in members of the transforming growth factor-β (TGF-β) family, nerve growth factor, and platelet derived–growth factor.

The anterior pituitary gland in a mature animal has several different types of endocrine cells, each of which secretes particular hormones. LH and FSH are synthesized in the gonadotrope cells of the anterior pituitary, with populations of cells synthesizing either LH or FSH, or both. This ability of some gonadotropes to produce more than one hormone makes them unusual in relation to the other endocrine cell types in the pituitary such as the corticotropes, thyrotropes, lactotropes, and somatotropes, each of which synthesizes and secretes largely a single tropic hormone in the adult. During development, however, it is likely that the different pituitary cell types arise from a common cell type under the control of cell-specific transcription factors that determine the temporal expression patterns of the hormonal genes in the pituitary.

LH and FSH are secreted in different patterns under different physiological circumstances, and the expression of the genes that encode them is also regulated differently under different conditions. GnRH provides the major stimulatory drive for expression of the β-subunit genes, and the steroid hormones, in general, have negative regulatory effects. The peptides, inhibin and follistatin, negatively regulate the expression of FSHβ, and activin stimulates expression of the *FSHβ* gene.

The LH/CG (LHR) and FSH receptors (FSHR) are members of the seven membrane–spanning domain, G-protein-linked receptor family. LH and hCG bind to the same receptor. Many of the receptors in this family have very short, extracellular amino termini, but the LHR and FSHR are unusual in that they have very long amino termini for hormone binding. The genes for LHR and FSHR are located on human chromosome 2p21 and 2p21-16, respectively. The LHR and FSHR genes are encoded by 11 and 10 exons respectively, with the last exon encoding the seven membrane–spanning domains and

the carboxy-terminal intracellular region. Exon 1 encodes the signal peptide to direct the newly synthesized protein to the luminal side of the endoplasmic reticulum and eventually to the cell membrane. Exons 2–9 of the FSHR and 2–10 of the LHR confer the hormone specificity and binding. These extracellular domains have a number of copies of an imperfectly repeated sequence of approximately 25 amino acids known as leucine-rich repeats. The functional significance of this structure is not known, but it may be involved in cell–cell or protein–protein interactions. There are also a number of potential N-linked glycosylation sites in the extracellular domains of these receptors but their role has not been elucidated. It has been suggested but not proven that to transmit its signal, the hormone bound to the extracellular domain interacts with the extracellular loops of the transmembrane segment. It is clear, however, that the third intracellular loop and the cytoplasmic tail are involved in G-protein coupling.

Relatively little is known about the transcriptional control of the gonadotropin receptor genes. For example, the FSHR gene of the rat and human has no TATA or CCAAT elements, no GC box motifs, and no CRE, AP-2, or methylation sites in its 5′-flanking region. A consensus E box sequence has been identified that binds upstream regulatory factors (USFs), members of a helix–loop–helix family that controls growth and differentiation. There is evidence that a site in the 3′-region for the E2F transcription factor may be important for promoter activity.

Both receptors are coupled to the G_s-protein that activates adenylyl cyclase leading to an increase in intracellular cAMP. However, there is accumulating evidence that both receptors can interact with G-proteins other than G_s such as $G_{q/11}$, G_{13}, and G_i. Both receptors can also activate other signal transduction pathways that involve phophoinositide turnover, intracellular calcium levels, and mitogen-activated kinases (MAPK).

After hormonal stimulation, the LHR and FSHR desensitize such that the efficiency of hormonal signaling is decreased. This occurs because of uncoupling of the receptor from the G_s-protein, internalization of the receptor resulting in a decrease in receptor number on the cell surface, and a decrease in receptor synthesis. Part of the mechanism of uncoupling involves binding of the receptor to inhibitory proteins called arrestins and targeting to clathrin-coated pits, but the details of this process are still under investigation.

2.2.2 Roles of Gonadotropins in Ovarian Functions

Both gonadotropin receptors are expressed in the ovary, and both can be detected as multiple transcripts that may arise as a result of the use of multiple transcription start sites or alternate polyadenylation signals. Both receptors have been shown to exhibit alternate splicing of the first 9 or 10 exons, and some of these transcripts would give rise to truncated peptides. It is not clear if these truncated forms of the receptor are translated, or if they have any functional significance, particularly during different phases of folliculogenesis.

FSHR are confined to the cell membranes of granulosa cells in the ovary, whereas LHR are found on the theca interna cells, the granulosa cells, and the luteal cells. In the case of granulosa cells, expression of the LHR occurs only at the late stages of follicular development during the antral/tertiary period, and is the result of stimulation of the cells by FSH, E2, and IGF-1. This cellular compartmentalization of gonadotropin receptors underlines the

"two cell, two gonadotropin" model of estrogen synthesis by the ovarian follicle. The follicle consists of an inner avascular granulosa cell layer within a basement membrane, surrounded by an outer vascular thecal cell layer. LH stimulates production of the precursor androgen by stimulating P450c17 in the theca interna. The granulosa cells, which lack the P450c17, do have the P450arom, which, under the influence of FSH, converts the thecal androgen to estrogen. Thus, both cell types and both gonadotropins are crucial for estrogen production during early folliculogenesis. Later in folliculogenesis, at the antral or tertiary stage, the granulosa cells acquire the capacity to respond to LH, which also regulates P450arom expression.

Both gonadotropins are essential for complete folliculogenesis, but in different ways and at different times. Neither gonadotropin is essential for the initiation of growth of resting primordial follicles into the follicular growth trajectory. FSH is not essential but may be facilitatory in the growth of primary and secondary preantral follicles. FSH is essential for the formation of healthy antral follicles, their selection as preovulatory follicles, and their survival from atresia. The mechanism by which FSH influences folliculogenesis includes stimulation of estrogen production, proliferation of granulosa cells by action on cyclin D2, and interacting with estrogen and IGF-1 to facilitate differentiation (see below). LH is necessary to stimulate the theca cells to produce androgen substrate for estrogen production, subsequently to drive the estrogen production in granulosa cells of selected antral follicles, and to cause ovulation and luteinization.

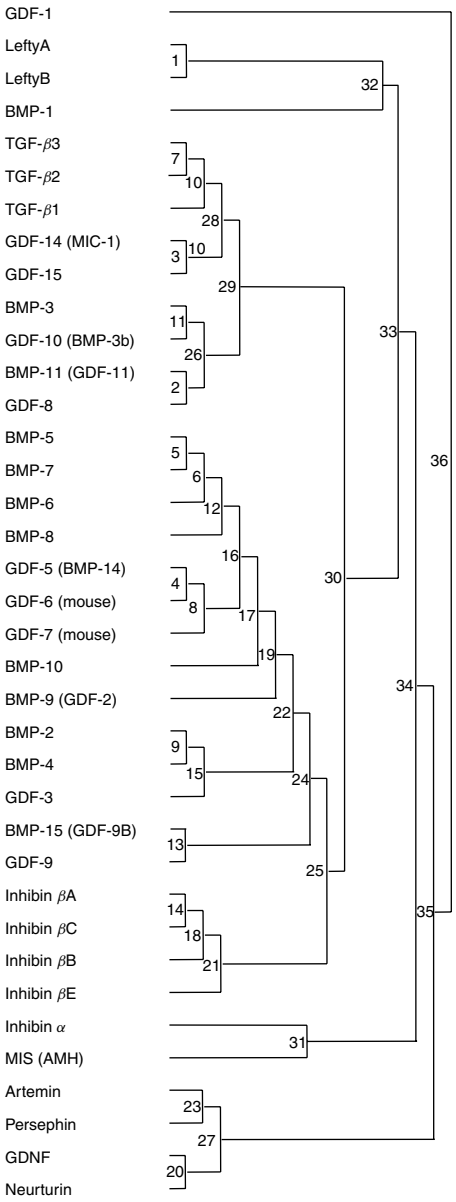
The mechanisms by which E2 and IGF-1 interact with FSH to enhance folliculogenesis are not clear, but probably involve an influence of FSH on the IGF-1 signal transduction pathway. The classic action of FSH is via the cAMP/protein kinase-A pathway to stimulate gene transcription. More recently, it has been shown that FSH can influence the MAPK pathway used by IGF-1 in granulosa cells by an action of cAMP through cAMP exchange proteins or GEFs on PI-3-kinase. Members of the forkhead (FOX) family of transcription factors are downstream targets of the IGF-1 pathway, and both FSH and E2 enhance expression of the gene for forkhead homolog of rhabdomyosarcoma (FKHR) and its protein in granulosa cells of developing follicles. Furthermore, E2 enhances expression of components of the IGF-1/PI3K/PDK1 pathway and expression of ERβ, indicating that E2 and IGF-1 may form an autocrine regulatory network in conjunction with FSH in developing follicles. FKHR has been linked to proliferation of granulosa cells, but the targets of FKHR are not known. The IGF-1/PDK1 pathway has been linked with cell survival. This may be the mechanism that FSH enhanced by E2, influences granulosa cell survival and thereby prevents atresia, whereas the action of FSH via the cAMP/PKA pathway facilitates differentiation of granulosa cells.

2.3 The Transforming Growth Factor β (TGF-β) Superfamily System

2.3.1 TGF-β Superfamily

TGF-β was described originally as a factor that induced normal rat kidney fibroblasts to form colonies in soft agar in the presence of epidermal growth factor (EGF). Subsequently it was found to belong to a family of multifunctional growth factors with diverse biological activities including cell growth, cell death

or apoptosis, cell differentiation, and extracellular matrix (ECM) synthesis. They play important actions in embryonic development, tissue remodeling, and wound healing, and the peptide and its receptors can be found in almost all cell types.



Five forms of TGF-β have been cloned, though only TGF-β_1, TGF-β_2, and TGF-β_3 have been found in the mammalian ovary. Each is a disulfide-linked homodimer with a molecular weight of 25 kDa in the unreduced form. Each monomer is 112 to 114 amino acids long and occupies the carboxy-terminal sequence of its precursor. There is a 70 to 80% sequence homology between the monomers, and there is complete conservation of the nine cysteine residues in each monomer. TGF-β generally is secreted in a biologically inactive, latent form, noncovalently associated with a dimer of the pro region of the precursor. The TGF-β superfamily of peptides is now used to describe a large group of extracellular, apparently disparate growth factors by virtue of their 30 to 40% amino acid homologies to TGF-βs (Fig. 5). They include the inhibins and activins, Müllerian-inhibiting substance, bone morphogenetic proteins, growth differentiation factors (GDFs), the decapentaplegic complex of *Drosophila*, *nodal* and *dorsalin-1* in mice, and *ceg-1* in *Caenorhabditis elegans* and *Drosophila*. Members of this superfamily share a number of similarities, including their synthesis as prepropeptide precursors with an N-terminal signal peptide, a middle prodomain followed by a mature peptide domain, as well as the formation of homo- or heterodimers

Fig. 5 TGF-β superfamily members. Mature peptide amino acid sequences of various human TGF-β superfamily members were aligned using GeneWorks program (IntelliGenetics, Inc.). Mouse GDF-6 and GDF-7 were also included in the analysis, as human GDF-6/7 was similar to GDF-5, also called cartilage-derived morphogenetic protein-1. Alternative names for some GDFs or BMPs were shown in parenthesis. Numbers on the hierarchical tree indicate the decreasing order of protein homologies.

through intermolecular disulfide bonds between conserved cysteine residues. Various members of each subfamily have been identified as having a regulatory role in the female reproductive system (Table 2).

In the ovary, TGF-β is expressed in follicular cells and has both proliferative and cytodifferentiation actions on granulosa cells. TGF-β can stimulate production of inhibin A and B by dispersed ovarian cells of postnatal rats, and like activin, TGF-β actions may be age-dependent.

The inhibin/activin family Inhibin was identified originally as a water-soluble testicular extract that prevented the hypertrophy of pituitary cells in response to castration. This definition was subsequently refined to designate an activity capable of selective suppression of FSH secretion, and on this basis, inhibin was isolated from ovarian follicular fluid and identified as a glycosylated heterodimer consisting of an α- and a β-chain joined by disulfide bonds. Like TGF-β, the mature dimer consists of the C-terminal sequences of a larger precursor of each chain, having a molecular weight of 31 to 32 kDa, although larger (e.g. 51, 58, 64, 105 kDa) biologically active forms exist. The α-chain precursor of 366 amino acids in the human is encoded by a single gene with only one intron, and the homology of the mature peptide (133 amino acids) is between 85 and 96% for human, bovine, ovine, and porcine specimens. The seven cysteine residues are totally conserved between species, but the human α-chain contains two potential N-linked glycosylation sites compared to one in the animal species. There are also other molecules such as αN, derived from the N-terminal end of the precursor of the α-chain, which do not have properly defined biological roles. There are five distinct forms of the β-chain (β_A, β_B, β_C, and β_E in mammals, and β_D in *Xenopus* sp.), and the β-chains in human are each coded by a single gene containing one intron. Only the β_A- and β_B-chains have been shown to dimerize with the α-chain, thereby giving rise to two isoforms of inhibin – inhibin A and inhibin B respectively. The human precursor peptides for β_A and β_B are 426 and 407 amino acids, respectively. The homologies of the mature β-chains (116 and 115 amino acids respectively) exceed 95%, and the nine cysteines are conserved. Indeed, the distribution of the cysteine residues in the α-, β_A-, and β_B-chains are very similar among the three peptides and other family members. Both inhibin A($\alpha\beta_A$) and inhibin B ($\alpha\beta_B$) have FSH-suppressing activity.

At the time when inhibin was being isolated from ovarian follicular fluid, an activity was found that stimulated FSH secretion. This activity, called activin, was identified as a nonglycosylated dimer of the β-chains with a molecular weight of 25 kDa. Activin exists as three isoforms,

activin A ($\beta_A\beta_A$), activin AB ($\beta_A\beta_B$), and activin B ($\beta_B\beta_B$), all of which appear to have similar FSH-stimulating activity. It is now known that activin is a pleiotropic regulator in many tissues including the developing embryo, where it acts as an inducer of the mesoderm, and in the bone marrow, where it is an erythroid-differentiating factor. Transgenic mice deficient for the inhibin β_B-subunit produced offspring, but the animals had developmental and reproductive disorders. There was a failure of eyelid fusion, and whereas the male offspring bred normally, the offspring of the females had high perinatal mortality. Furthermore, expression of the β_A-subunit was upregulated in the ovaries of the females. These data suggest that activin β_B plays a role in fetal development and is critical for female fecundity, but is not essential for mesoderm formation. In the ovary, activin is produced by the granulosa cells, and the pattern of expression of the activin subunits mRNA changes during folliculogenesis. Numerous functional studies support a role for activin in folliculogenesis. Activin can promote granulosa cell proliferation, potentiate FSH actions by increasing the FSH receptor expression on granulosa cells, and modulate steroidogenesis in both granulosa and theca cells. The actual function of activin in folliculogenesis is sometimes obscured by its age-specific effects. For example, it was shown that activin A stimulates growth of follicles from immature animals but blocks the FSH-induced growth of preantral follicles from adult animals. Nevertheless, a recent study suggested that activin from secondary follicles may cause small preantral follicles to remain dormant.

Follistatin or FSH-suppressing activity was also isolated from ovarian follicular fluid but was found to be unrelated structurally to inhibin. It exists in up to six isoforms (31–42 kDa), which arise as a result of a combination of alternate splicing of its mRNA and variable glycosylation of the mature peptide. It is encoded by a single gene, consisting of six exons, with the alternate splice site located in exon 5. All the follistatin genes and cDNAs from different mammalian species sequenced to date are more than 95% homologous at the amino acid level, with a homolog in *Xenopus* having 85% homology. The mature follistatin proteins consist of four contiguous domains, each encoded by a different exon; the last three domains are 52% homologous with each other and are also structurally related to EGF and to a pancreatic secretory inhibitor. Follistatin derives its FSH-suppressing activity from its ability to bind activin; it is expressed in the germ cells, embryo, pituitary, ovary, and placenta, as well as the brain, adrenal, bone marrow, and spleen, although not always coincidently with activin. It is also highly expressed in the kidney and pancreas, where the inhibin β-subunit mRNA has not been detected. Neither follistatin nor inhibin β-subunit is expressed in the liver. In the ovary, follistatin is expressed by the granulosa cells, and its basal expression increases with increased granulosa cell differentiation. Follistatin production can be upregulated by FSH and activin, but only in partially or totally undifferentiated granulosa cells, and not in fully differentiated cells. Since follistatin counteracts activin activities, its pattern of expression is consistent with the suggested hypothesis that there is a decreasing activin ''tone'' within follicles as they develop owing to higher levels of follistatin. This could have implications for activin access to its receptor signal transduction system as follicles mature, despite the presence of all the signaling system components. An analysis

of the activin and follistatin contents of individual follicles at defined stages of development is needed to support this hypothesis.

The BMP/GDF family BMPs were originally isolated by their ability to induce ectopic bone and cartilage formation *in vivo*, but it is now evident that BMPs are also multifunctional regulators of morphogenesis during development in vertebrates and invertebrates. GDF-1 was cloned initially from an 8.5-day mouse embryo in a search for extracellular factors essential for mammalian embryonic development. Subsequently, numerous family members have been discovered and have been classified into various subgroups on the basis of their sequence homologies. The BMPs/GDFs family now constitutes the single largest family within the TGF-β superfamily, and also includes BMP-like molecules from *Drosophila* sp. and *C. elegans and Xenopus* sp.

Recent studies on naturally occurring BMP/GDF mutations in sheep, as well as the creation of knockout mouse models have indicated the important role these factors play both in folliculogenesis and in embryonic development. BMP-4 and BMP-8b produced by the extraembryonic ectoderm appear to be essential for the generation of primordial germ cells in the mouse. BMP-4 mRNA, together with BMP-7 mRNA, is also expressed in the adult ovary, especially in thecal cells of healthy Graafian follicles. Both BMP-4 and BMP-7 increase the FSH-induced estradiol production by granulosa cells, whereas the FSH-induced progesterone production is decreased, leading to the possibility that these factors may function as luteinization inhibitors in the Graafian follicle. Genetic deletion in the mouse, of BMP-2, BMP-4, or BMP-7 caused embryonic (BMP-2, BMP-4) or perinatal (BMP-7) lethality.

GDF-9 is produced by the oocytes and targeted deletion of the *GDF-9* gene resulted in female infertility due to the failure of the theca cells to organize abnormal oocyte growth and decreased granulosa cell proliferation, which resulted in a block of folliculogenesis at the primary follicle stage. *In vitro* studies have shown that oocyte-derived GDF-9 stimulates the proliferation and suppresses the FSH-induced differentiation of rat granulosa cells *in vitro*.

BMP-15 (also called GDF-9b) is an oocyte-derived factor, which is expressed from the primary follicle phases onward. A natural X-linked mutation in sheep identified BMP-15 as an essential factor for female fertility. Intriguingly, BMP-15 has a dose-dependent effect since homozygous mutants have their follicular development arrested at the primary stage, whereas heterozygous animals have increased ovulation rates resulting in multiple pregnancies. Although the exact function of BMP-15 is still unknown, it has been shown to modulate FSH action in rat granulosa cells by suppressing FSH receptor expression.

BMP-6 is another TGF-β member expressed in the oocyte. Until recently, no information was available on its putative biological function in the ovary. *In vitro* studies using rat granulosa cells have demonstrated that BMP-6 has no effect on their proliferation, but inhibits FSH-induced progesterone production without affecting FSH-induced estradiol synthesis, which is reminiscent of a BMP-15 activity. However, in contrast to BMP-15, BMP-6 does not modulate the expression of the FSH receptor leading to the suggestion that, in addition to the theca-derived BMP-4 and BMP-7, the oocyte-derived

BMP-6 and BMP-15 could also function as inhibitors of luteinization. BMP-6 knockout mice, however, remain viable and are fertile.

MIS MIS, also called *anti-Müllerian* hormone (AMH) or Müllerian-inhibiting factor (MIF), is the testicular factor responsible for regression of the Müllerian primordia, the first step of male somatic differentiation. Native MIS is a high molecular weight (140–144 or 280–290 kDa) glycoprotein, formed by the assembly of dimers or tetramers of a 70 or a 72 kDa monomer. Like other members of the TGF-β superfamily, the MIS monomer is derived from a larger 546 amino acid precursor in which the mature form is at the C-terminal end of the molecule. The 140-kDa homodimer is further processed to a noncovalent complex of 110 and 25 kDa dimers, although it is not known whether this step is required for activation of the biological activity of MIS. The MIS gene, located on human chromosome 19, p13.3, is only 2.7 kb and is encoded by 5 exons. There are multiple transcription initiation sites, perhaps because the human MIS promoter lacks consensus TATA and CAAT boxes, similar to many so-called housekeeping genes.

In males, MIS is produced by the testicular Sertoli cells from the time of fetal sex differentiation to puberty, whereas in females, it is produced by the granulosa cells from the antral follicles of the ovary from the time of birth to the end of ovarian activity. Synthesis of MIS by granulosa cells is low compared with the Sertoli cell of the testis. In rodents, expression of MIS is highest in the granulosa cells of the follicles during the preantral and small antral stage, with atretic follicles having decreased or with no expression of MIS. It is completely absent in the corpus lutea, and is never found in the primordial follicles, theca cells, oocytes, and the interstitium. The physiological significance of expression of MIS in the female gonads, especially in the adult, is unclear, although the specific patterns of MIS expression suggest that MIS might play a role in follicle development and function. There is data to suggest that MIS might affect development of the fetal ovary. For example, transgenic female mice chronically overexpressing MIS undergo total Müllerian regression, and most lack ovaries; where there is ovarian tissue, it is severely depleted of germ cells and contains structures resembling seminiferous tubules. MIS has also been shown to inhibit aromatase activity in fetal ovaries. Further insights on the role of MIS in the ovary came from MIS-knockout mice. Female MIS-deficient animals are fertile and although they showed no obvious gross ovarian abnormalities, the ovaries of adult females showed premature loss of primordial follicles compared to that of wild-type animals. Further *in vitro* studies indicated that MIS acts as an inhibitory growth factor in early folliculogenesis to block the initiation of primordial follicle growth, probably through the paracrine influence of granulosa cells on the primordial follicles.

2.3.2 TGF-β Superfamily Receptors

Almost all of the TGF-β superfamily of ligands uses a conserved signaling pathway involving a family of structurally similar group of receptors, the TGF-β superfamily receptors. These cell surface, single-pass transmembrane receptors contain intracellular kinase domains that phosphorylate serine and threonine residues. There are two distinct receptor subtypes (type I and type II), which need to interact with one

another to produce a cellular response. Ligand binding induces type I and type II receptors in the cellular membrane to associate, and causes the type II to phosphorylate the type I receptor, thereby activating its kinase domain. The activated type I receptor then phosphorylates the SMAD family of intracellular mediators, of which there are 8 members (Smad 1–8) divided into 3 distinct classes based on their functional properties. The receptor-regulated SMADs (or R-Smads) comprising of Smad-1, -2, -3, -5 and -8 are anchored to the cell membrane through association with membrane-bound proteins, including SARA (SMAD anchor for receptor activation). R-Smads, when directly phosphorylated on two conserved serine residues at the C-terminus by the activated type I receptor kinase, then dissociate from the receptor complexes and SARA to form oligomeric complexes with a second class of SMADs called copartner SMADs (Co-Smads) of which Smad-4 is the only member. These heteromeric complexes translocate and accumulate in the nucleus where they associate with one of many DNA-binding proteins including various transcriptional coactivators and corepressors to regulated target gene transcriptions. A third class of SMADs, the inhibitory SMADs (I-Smads) of which Smad-6 and -7 are the two members, inhibit the signals from the serine/threonine kinase receptors to antagonize signal transduction. I-Smads constitute an autoinhibitory signaling pathway as their expression is induced by TGF-β superfamily members themselves.

There are 5 type II receptors in vertebrates, each of which can pair up with one of 7 type I receptors (also known as activin-like receptor kinases, or ALKs) to mediate signaling (Table 3). Recent studies have indicated that the active signaling receptor complex is made up of two type I and two type II receptors, forming a heterotetrameric complex binding two molecules of the ligand. While ligand-binding specificity is determined largely by the type II receptors (and sometimes in combination with the type I receptors), intracellular signaling to SMADs is entirely determined by the type I receptor. There are two

Tab. 3 Signaling components of the TGF-β superfamily members that are important in the female reproductive system. Receptor subtypes and R-SMADs utilized by each ligand are shown. Alternate names for some ALKs are shown in parenthesis.

Ligands	*Type II receptor*	*Type I receptor*	*R-SMADs*
TGF-β	*T*β RII	ALK-1 ALK-5 (*T*β RI)	Smad-2, Smad-3
Activin	*Act* RIIA *Act* RIIB	ALK-4 (*Act* RIB)	Smad-2, Smad-3
Nodal	*Act* RIIB	ALK-4 (*Act* RIB) ALK-7	Smad-2, Smad-3
BMPs	*BMP* RII *Act* RIIA *Act* RIIB	ALK-2 (*Act* RIA) ALK-3 (*BMP* RIA) ALK-6 (*BMP* RIB)	Smad-1, Smad-5, Smad-8
MIS	*MIS* RII	ALK-2 (*Act* RIA) ALK-3 (*BMP* RIA) ALK-6 (*BMP* RIB)	Smad-1, Smad-5, Smad-8

intracellular signaling pathways leading to SMADs activation; the ALK-4, -5 and -7 type I receptors phosphorylate Smad-2 and -3 which transduce TGF-β-like signals (like TGF-β, activin and nodal), and the ALK-1, -2, -3, -6 type I receptors phosphorylate Smad-1, -5 and -8 to mediate BMP-like signals (BMP-2, -4, -6, -7, and MIS).

The role of TGF-β receptors in the ovary has not been extensively studied. In the human ovary, receptors TβRI and TβRII were located in the granulosa, theca, and interstitial cells, with patterns of expression significantly different from each other.

Similarly, information on BMP signaling in the ovary is only now beginning to emerge. BMP receptor mRNAs are present in the ovary, with the strongest expression in granulosa cells and oocytes, and this is consistent with the observed BMP actions on granulosa cells. The importance of BMP signaling in the ovary is demonstrated by natural mutations and loss-of-function studies of the BMP receptors. BMPRIB (ALK-6) deficient mice showed that the absence of BMPRIB signaling causes infertility with several reproductive defects, including decreased levels of P450arom expression in granulosa cells. Studies on the Booroola sheep revealed a naturally occurring point mutation in the *BmprIB* gene, which is associated with increased ovulation rate; however, the consequence of this mutation on BMPRIB activity is currently unknown. This is especially relevant since the phenotype of the BMPRIB deficient mice is opposite to the phenotype of the Booroola sheep, and may suggest that the sheep model carries an activating mutation of the BMPRIB.

In the adult rat ovary, MISRII mRNA is found mainly in granulosa cells from preantral and small antral follicles, but primordial follicles seem to be deprived of MISRII, which is not consistent with the proposed role of MIS on the regulation of primordial follicle recruitment. This suggests that either MIS has a secondary effect on primordial follicles or that MIS signals through alternative pathways where MISRII is not involved.

In the ovary, activin is probably the most studied member of the TGF-β superfamily. Studies with radiolabeled activin revealed binding sites on rat granulosa cells during all phases of the ovarian cycle, as well as theca cells in developing follicles. Consistent with this, the expression of activin receptor mRNAs has been detected in the ovaries at various developmental stages (Table 4).

Tab. 4 Expression of activin receptor transcripts in the ovary.

Activin receptors	*Localization*	*Species*
Act RII	Oocytes	Rat, mouse
	Granulosa cells	Rat
	Granulosa-luteal cells	Human
Act RIIB	Oocytes	Mouse
	Granulosa cells	Human, rat
Act RIA (ALK-2)	Oocytes	Rat
	Antral and preantral follicles	Rat
	Granulosa-luteal cells	Human
Act RIB (ALK-4)	Oocytes and cumulus cells	Human, mouse
	Granulosa-luteal cells	Human

Although inhibin is a potent regulator of activin signaling, the presence of inhibin-specific receptors capable of activin-independent signaling has not been identified. Recent studies, however, have indicated that betaglycan, a membrane-bound proteoglycan originally identified as the type III receptor for TGF-β, can bind inhibin with high affinity and can mediate inhibin functional antagonism of activin signaling. Consistent with this, expression of betaglycan and its transcripts has been localized to different regions of the rat reproductive axis, in particular, to all cell types of the pituitary, being greatest in the gonadotropes, the target sites of inhibin in the endocrine control of FSH. Moderate levels of betaglycan mRNA were also detected in ovarian granulosa cells with lower expression in the thecal layer and the oocyte. In the testes, betaglycan mRNA was observed in the Leydig and tubule-specific germ cells.

2.4 Insulin-like Growth Factor (IGF) System

2.4.1 IGFs, IGF-binding Proteins (IGFBPs) and IGF-receptors

IGF-I and IGF-II are single-chain polypeptides, which are structurally related to insulin and play an important role in growth and development. Both IGFs play essential roles in developmental growth, as demonstrated by gene knockout experiments in mice. Deletion of the IGF-I gene caused growth retardation, and most animals died after birth. Those that survived are severely growth retarded with developmental defects including impaired ovarian follicular growth, suggesting that IGF-I is critical for prenatal and postnatal growth and development. In contrast, IGF-II null mice were born small but showed normal postnatal growth suggesting that IGF-II might be primarily responsible for intrauterine growth. IGF-I is synthesized by a variety of cell types, and plays a role in ovarian folliculogenesis by potentiating FSH-stimulated cAMP production (see Sect. 2.2.2), aromatase activity, and LH receptor expression by granulosa cells.

The IGF system is composed of three different component systems – the two IGF ligands (IGF-I and IGF-II), two receptors (IGF-I or type I receptor, and IGF-II or type II receptor), and six IGF-binding proteins (IGFBP-1 to -6). In addition, there are specific IGFBP proteases as well as IGFBP-related proteins (IGFBPrP). Altogether, these IGF system components determine and modulate the net actions of IGFs in target tissues.

2.4.2 Gene Structure and Expression in the Ovary

IGF-1 and IGF-II The human IGF-1 gene is located in chromosome 12 (Table 5), and has six exons spanning 80 kb. Owing to two alternative translation start sites in exons 1 and 2, different mRNA species

Tab. 5 Chromosomal localization of the human genes for the various IGF components.

IGF components	*Chromosomal localization*
IGF-I	12q22-q23
IGF-II	11p15.5
IGF-R1	15q25-q26
IGF-RII	6q26
IGFBP-1	7p13-p12
IGFBP-2	2q33-q34
IGFBP-3	7p13-p12
IGFBP-4	17q12-q21.1
IGFBP-5	2q33-q36
IGFBP-6	12q13
ALS	16p13.3

of 7.6, 1.3, and 1.1 kb are present in different proportions in different tissues. Although protein-coding sequences are found in exons 3 and 4, alternative splicing of exon 5 and 6 give rise to preproIGF-IA and IGF-IB respectively. IGF-I mRNA showed low and stage-specific expression in the ovary, being detectable only in the thecal cells of small antral follicles but not in the dominant follicle. IGF-I mRNA is absent is the granulosa cells of both antral and dominant follicles. Immunoreactive IGF-I, however, has been found in follicular fluids, but at levels lower than that present in peripheral plasma. It is likely that the follicular fluid IGF-I may be derived from the circulation suggesting that circulating IGF-I may regulate folliculogenesis in an endocrine manner, rather than intraovarian IGF-I acting locally.

The IGF-II gene is located in chromosome 11 contiguous to the insulin gene. It has a complex structure comprising of 4 promoters, 9 exons, and 2 polyadenylation sites, resulting in the expression of multiple IGF-II mRNA transcripts of 6, 5.3, 5, 4.8, 2.2, and 1.8 kb. In addition, expression of the IGF-II gene also showed transcriptional repression of the maternal allele due to genomic imprinting. Unlike IGF-I, IGF-II is the principal IGF in human ovarian follicles. IGF-II mRNA is expressed in the thecal cells of small antral but not dominant follicles. Granulosa cells from dominant but not small antral follicles expressed IGF-II mRNA. This indicated that as the follicles developed, the source of IGF-II was switched from thecal to granulosa cells. Expression of the IGF-II mRNA in the granulosa cells is regulated by gonadotropins and cAMP analogs. Follicular fluid contains immunoreactive IGF-II, at levels higher than that present in peripheral plasma, indicating the intraovarian source of IGF-II. Since there appears to be a coordinate regulation of IGF-II mRNA and the cholesterol side chain cleavage enzyme, P450scc, in human steroidogenic tissues, locally produced IGF-II may regulate steroidogenesis and the subsequent development of the dominant follicles.

IGF-receptors Although most of the biological functions of IGF-I and IGF-II are mediated by the type I IGF receptor, both type I and type II receptors are expressed in the ovary. The IGF-I receptor (type I) shows ligand-dependent tyrosine kinase activity and autophosphorylation, and has considerable structural and functional similarity to the insulin receptor but has higher affinity for IGF-I and IGF-II than for insulin. The signaling receptor is a heterotetramer comprising two α- and two β-subunits, and shows considerable overlap in signal transduction events to that of the insulin receptor including tyrosine phosphorylation of the β-subunits, interactions with docking proteins like IRS and Shc, and activation of PI-3 kinase and MAPK. Mice lacking the IGF-I receptor gene are small at birth and die shortly afterwards. Patients with an allelic deficiency in the type I IGF receptor gene show intrauterine and postnatal growth restriction, indicating that IGF-I is essential for embryonic growth. In the ovary, type I receptor mRNA is expressed in the granulosa cells of both small antral and dominant follicles, and is absent in thecal cells.

In contrast, the type II receptor (also known as the cation-independent mannose-6-phosphate receptor) is a single integral membrane protein, which can interact with a diverse group of ligands including peptide growth factors and lysosomal enzymes. It has a higher affinity for IGF-II than IGF-I and does not bind

insulin. Binding of IGF-II to the receptor results in the rapid internalization of IGF-II and its subsequent degradation by the lysosomes. This degradative process appears to be an important regulator of IGF-II activity, since mice deficient in the type II receptor show elevated IGF-II levels and die *in utero* due to somatic overgrowth and organ abnormalities suggestive of overstimulation from the type I receptor. Besides degrading IGF-II, recent studies have indicated that the type II receptor may have IGF-II-dependent signaling function through G protein–coupled receptor pathways.

Unlike the type I receptor mRNA whose expression is limited to the granulosa cells, the type II receptor mRNA is expressed in both the thecal and the granulosa cells from both antral and dominant follicles. The differential presence of both ligand and receptor in the same cells suggested that in small antral follicles, IGF-II could act in an autocrine manner in thecal cells, but not in granulosa cells. In the dominant follicles, granulosa-derived IGF-II can also act in an autocrine manner in granulosa cells.

IGFBPs In plasma, almost all of the IGFs circulate as high molecular weight complexes. The majority of the IGFs are present in a 150 kDa ternary complex comprising one molecule each of IGF, IGFBP-3 (the predominant IGFBP in serum) or IGFBP-5, and an 85 kDa glycoprotein, the acid-labile subunit (ALS). Plasma also contains lower molecular weight complexes of ~50 kDa, which are made up of several other IGFBP species (IGFBP-1, -2, -4 and -6) that are incompletely saturated with IGFs leaving virtually no free IGFs in circulation. This circulating source of IGFs, which has been regarded as contributing to the endocrine effects of IGFs, are largely determined by growth hormone status.

In extravascular biological fluids, however, most IGFs are bound to the IGFBPs as binary complexes since the ternary complex is unable to cross the endothelial barrier. IGFBPs function to determine the bioavailability of the IGFs, and therefore modulate its actions locally. The family of 6 IGFBPs (IGFBP-1 to -6) are structurally related to each other, and bind IGF-I and IGF-II with high affinity but share no homology with the IGF-receptors. These proteins are encoded by different genes, and have different biochemical and biological characteristics, which are due to differences in their primary structure.

All IGFBPs except IGFBP-6 have been found in the granulosa and thecal cells of the ovary (Table 6). Levels of IGFBPs in the follicular fluids vary depending on the developmental stage of the follicle.

IGFBP-1: Though found at very low concentrations in adult serum, it is the predominant IGFBP present in human amniotic fluid. It has equal affinity for both IGF-I and IGF-II, and is known to be serine-phosphorylated to varying extents depending on the tissue source. Dephosphorylated forms have a lower affinity for IGF-I and are thought to potentiate IGF actions, whereas phosphorylated forms may inhibit the mitogenic actions of IGFs.

The *IGFBP-1* gene is located on human chromosome 7p14-p12 where it is contiguous in a tail-to-tail configuration with that of *IGFBP-3*. The gene spans 5.2 kb and has 4 exons which contain all the coding regions of the gene. In the human ovary, IGFBP-1 is found only in the granulosa cells of dominant follicles, and is not present in the theca or small antral follicles. IGFBP-1 is also expressed in the corpus luteum.

Tab. 6 Expression of the various IGF components in the human female reproductive system. + indicates detectables as mRNA transcripts, − indicates no mRNA transcripts were detected.

IGF components	*Endometrial cells*		*Small anthral follicles*		*Dominant follicles*	
	Proliferative	*Secretory*	*Thecal*	*Granulosa*	*Thecal*	*Granulosa*
IGF-I	+	+	+	−	−	−
IGF-II	+	+	+	−	−	+
IGF-R1	+	+	−	+	−	+
IGF-RII	+	+	+	+	+	+
IGFBP-1	−	+	−	−	−	+
IGFBP-2	+	+	+	+	+	−
IGFBP-3	+	+	+	−	+	+
IGFBP-4	+	+	+	+	+	+
IGFBP-5	+	+	+	+	+	+
IGFBP-6	+	+	−	−	−	−

IGFBP-2: This is the most abundant IGFBP in human fetal serum during mid-gestation. The human *IGFBP-2* gene contains 4 exons, and maps to chromosome 2q33-q34. It spans ~32 kb of chromosomal DNA, with the first intron covering about 27 kb in size. IGFBP-2 is expressed in both the granulosa and thecal cells of small antral follicles. In dominant follicles, IGFBP-2 is expressed only in the thecal cells, suggesting a developmental loss of IGFBP-2 expression in the granulosa cells as the follicles become dominant.

IGFBP-3: IGFBP-3 is the most abundant circulating IGFBP in the postnatal animal. Serum levels increase with postnatal age to peak at puberty, reaching as high as 4 $\mu g\,mL^{-1}$. Most of the IGFBP-3 in circulation, when occupied by IGF-I or IGF-II, are complexed with ALS to form a 150 kDa ternary complex. IGFBP-3 expression is transcriptionally regulated by the growth hormone, and serum levels of IGFBP-3 are dependent on the growth hormone status. In the ovary, IGFBP-3 expression is found in the theca of all follicles, and the granulosa cells of dominant follicles. The gene for IGFBP-3 maps to chromosome 7p12-p14, about 20 kb from the *IGFBP-1* gene. The gene spans 8.9 kb and contains 4 coding exons.

IGFBP-4: IGFBP-4 is predominantly expressed in the liver, which represents the single largest source of IGFBP-4 in the adult rat. It is one of the most abundant IGFBP transcripts in the mid- and late-gestational embryo, particularly in mesodermally derived tissues like smooth and striated muscles, lungs, liver, and to a lesser extent, the heart. In the ovary, IGFBP-4 is expressed in both the thecal and granulosa cells of all follicles, and is a potent inhibitor of IGF-II and FSH-stimulated steroidogenesis in granulosa cells.

IGFBP-5: In humans, IGFBP-5 circulates at ~15% of IGFBP-3 levels, and like IGFBP-3, can also form ternary complexes with ALS when bound to IGF-I or IGF-II. IGFBP-5 is characterized by the presence of the 18 cysteine residues conserved among IGFBP-1 to -4, and lacks N-glycosylation site or RGD sequence. It contains a stretch of mostly basic amino acid residues that may mediate the binding

of IGFBP-5 to extracellular matrix and glycosaminoglycans. The human *IGFBP-5* gene maps to region 2q33–34 of chromosome 2, 20–40 kb from the *IGFBP-2* gene in a tail-to-tail orientation. Like IGFBP-4, IGFBP-5 is expressed in the theca and granulosa cells of all follicles.

IGFBP-6: In the endometrium, IGF-I expression is elevated during the estrogen-dominated proliferative phase, whereas IGF-II expression is elevated in secretory endometrium. Type I and type II IGF receptor mRNAs are both present in endometrial stroma, but are relatively more abundant in endometrial epithelium; neither show distinctive cyclical changes.

2.4.3 Roles of IGFs in Ovarian Function

IGF is an important growth factor that plays both an endocrine and a paracrine role in mammalian ovarian follicular development, growth of dominant follicles, and follicular atresia. IGF-I amplifies gonadotropin hormone actions through increasing steroidogenesis by granulosa cells and granulosa cell proliferation. Although in humans, IGF-II is the predominant endogenous IGF produced locally in the ovary, its actions appear to be similar to that of IGF-I. In granulosa cells, IGFs promote basal estrogen secretion through stimulation of aromatase activity and aromatase mRNA expression. IGFs can also augment the FSH-stimulated estrogen and progesterone secretion. In thecal cells, IGFs also stimulate DNA synthesis and can promote testosterone and androstenedione production.

The actions of IGFBP in the human ovary appear to be similar to that seen from studies using experimental animal models. These actions of IGFBPs are largely antagonistic toward IGFs, suggesting that the predominant role of IGFBPs is to sequester locally produced IGFs from binding to the IGF-receptors. In this way, IGFBPs can antagonize gonadotropin actions, and high intracellular IGFBP levels can lead to follicle atresia.

2.5 Other Peptides/Enzymes

2.5.1 Endothelins

Endothelin was described originally as a product of endothelial cells that had a potent vasoconstrictor effect on vessels by means of an action on the smooth muscle cells. Subsequently, its sites of production have expanded considerably to include many epithelial cells in the pituitary, ovary, endometrium, myometrium, and placenta. The endothelins are a family of three peptides (ET-1, ET-2, ET-3), encoded by three separate mammalian genes that are related to the gene for sarafotoxin in snakes. Each isoform is a 21-amino acid peptide, derived by posttranslational processing from a larger precursor peptide of around 200 amino acids. The endothelin-converting enzymes (designated ECE-1 and -2) that perform these cleavages have been cloned, but their specificities are still unclear. They may, together with neutral endopeptidase, be responsible for degradation of the ETs. The ETs act through one of three receptors (ETA, ETB, ETC), each of which has been cloned. Each receptor has a different affinity profile for the ETs, with ETA binding preferentially to ET-1 and predominating on smooth muscle cells of blood vessels, whereas ETB binds both ET-1 and ET-2 and has a wider cellular distribution. It has been suggested that the different receptor subtypes are coupled to different transduction systems, since such a relationship could explain the pluripotent actions of ETs, which now

include mitogenic and hormone-releasing activities as well as vasoconstriction.

2.5.2 Oxytocin

The uterotonic and milk-ejecting activities of the posterior pituitary and corpus luteum of the ovary were first described at the beginning of this century, but it was not until the early 1950s that the activity was identified as oxytocin, a cyclic nonapeptide. It was discovered that oxytocin is released by exocytosis of secretory granules, which also contain a carrier protein called neurophysin 1, which, with oxytocin forms part of a larger precursor molecule. The single-copy genes in all species are similar in structure and contain three exons, with exon A encoding the signal peptide, oxytocin and the amino-terminal region of neurophysin (amino acids 1–9) and exons B (amino acids 10–76) and C (amino acids 77–93) encoding the remainder of the neurophysin. Complex posttranslational processing of the precursor molecule by exo- and endopeptidases, a carboxypeptidase B-like enzyme, and an amidation enzyme gives rise to neurophysin and several pre forms of oxytocin, which associate with the neurophysin in the secretory granule before release from the cell.

The oxytocin gene is expressed in the cell bodies of the supraoptic and paraventricular nuclei of the hypothalamus of all species, and the precursor is processed en route along the axons of the median eminence and pituitary stalk to the storage granules of the posterior pituitary. Oxytocin released from this source is involved in the milk ejection reflex and the stimulation of uterine contractions.

The pregnant uterus is highly sensitive to the uterotonic effects of oxytocin, and is clinically used to induce labor. Expression of oxytocin is found in the human amnion, chorion, and decidua. Although there appears to be no apparent increase in oxytocin levels in the maternal plasma or intrauterine tissues during the onset of labor, there is a dramatic increase in oxytocin receptor expression in the myometrium, indicating that increased uterine sensitivity to oxytocin at this stage is due to changes in receptor levels.

Expression of the oxytocin gene in the ovary, particularly the corpus luteum, is well documented in ruminants, where it is believed to play a role in inducing the release of the uterine luteolysin prostaglandin F2α, which is responsible for regression of the corpus luteum of an infertile cycle. Clear understanding is lacking, however, of the level of expression and production of oxytocin in the ovary of other species, particularly humans, and its physiological role.

A single class of receptor sites for oxytocin has been characterized on the principal target cells, smooth muscle of the reproductive tract and myoepithelial cells of the mammary gland, as well as on the endometrium of sheep and humans. The human oxytocin receptor gene cDNA has been cloned. It encodes a 388 amino acid–polypeptide with seven-transmembrane domains typical of G protein–coupled receptors and is a member of the arginine–vasopressin/oxytocin family of receptors. The mRNA was found in two sizes, 3.6 kb in breast and 4.4 kb in ovary, uterine endometrium, and myometrium. The levels of oxytocin receptor mRNA are high in the myometrium, the maternally derived decidual cells, and the chorionic trophoblast cells at term, consistent with its role in human labor. The oxytocin receptor mRNA is also expressed in the sheep uterus, particularly in the endometrium, where oxytocin is responsible for releasing prostaglandin F2α. In all these cases, expression of the oxytocin receptor mRNA is

coincident with detection of the receptor protein and binding activity.

2.5.3 Zona Pellucida Proteins

The zona pellucida or egg surface coat is a transparent extracellular matrix surrounding mammalian oocytes, and is important for successful folliculogenesis, to ensure proper fertilization by the sperm, and to protect the embryo as it moves along the oviduct to the uterus before implantation. The zona pellucida consists almost entirely of three glycoproteins called ZP1, -2, and -3. Mouse ZP2 (120 kDa) and ZP3 (83 kDa) are present as heterodimers along the filaments that make up the extracellular coat of the egg, and the filaments are interconnected by ZP1 (200 kDa), a dimer of identical polypeptides held together by disulfide bonds. ZP3 has been identified as the primary sperm receptor on the mouse egg. There is a 22 amino acid–signal sequence, and the mature protein contains 402 amino acids rich in proline, serine, and threonine residues, as well as N- and O-linked glycosylation sites that make up the final molecular weight. ZP3 is encoded by a single-copy 8.6 kb gene containing eight exons; it yields a 1.5 kb mRNA, which is expressed only in the oocyte. Maximum expression occurs during oocyte growth, with levels falling and becoming undetectable after fertilization.

Sperm binding to mouse eggs is an example of carbohydrate-mediated cellular adhesion. Once bound, the sperm undergoes the acrosome reaction, which removes their egg-binding proteins; to remain bound, the inner acrosomal membrane of the sperm binds to ZP2, which acts as a secondary receptor and allows the sperm to penetrate the zona pellucida and fuse with the egg plasma membrane. Once fertilization has occurred, structural changes in the zona pellucida ensure that no more sperm bind and penetrate the matrix, thereby preventing polyspermic fertilization of the oocyte. The fertilized embryo, prior to implantation, continues to be surrounded by the zona pellucida, which is critical for their survival and development. Gene deletion studies in mice confirmed the importance of the zona pellucida proteins in folliculogenesis. ZP-1 deficient mice are fertile but showed reduced litter sizes due to early embryonic lethality. ZP-2 and ZP-3 deficient mice are infertile as early follicle development was impaired.

2.5.4 Leukemia Inhibitory Factor

Leukemia inhibitory factor (LIF) is a pleiotropic cytokine of the interleukin-6 family, and was initially identified by its ability to inhibit the proliferation of a myeloid leukemic cell line by inducing differentiation. It is now known that the 45 to 56 kDa glycoprotein has multiple activities including causing acute phase response in hepatocytes; regulation of differentiation and proliferation of hematopoietic cell lines; remodeling bone; and regulating growth; and inhibiting differentiation of embryonic stem cells, primordial germ cells, adipocytes, and endothelial cells. In adult mice, the highest expression of LIF mRNA is found in the endometrial epithelial cells, with the glandular expression of LIF being regulated throughout the reproductive cycle. Its expression is independent of the presence of a blastocyst and occurs transiently in response to a rise in E2 on day 4 of pregnancy, just prior to implantation. This transient expression of LIF was shown to be essential for implantation as shown by transgenic mice lacking LIF expression. These animals conceive, but the blastocysts fail to implant and develop, although the blastocysts remain viable and will develop to term if transferred to a

wild-type female. In human and primates, LIF is expressed in the endometrium in a menstrual cycle-dependent manner, with maximal expression observed at the time of implantation. Expression of LIF is localized to the glandular and luminal epithelial cells. LIF mRNA is absent or occurs at low levels during the proliferative or preovulatory phase. LIF is also expressed by the endothelial cells of the fallopian tube.

2.5.5 Tissue Remodeling Enzymes

The ovary and the uterus are unique among organs in having regular cyclic remodeling of the tissues. In the ovary, this involves the processes of ovulation (development of the follicles progressing through to oocyte extrusion), and the formation and regression of the corpus luteum (Fig. 2). In the uterus, there is the sloughing and regeneration of the endometrium at menstruation, tissue remodeling at implantation, preparation of the uterus and cervix for birth, and their reconstruction after birth. A major part of this process involves degradation of the extracellular matrix (ECM) by matrix metalloproteinases, which together with their associated inhibitors (serum macroglobulins, and TIMPS, tissue inhibitors of metalloproteinases) act coordinately to regulate the site and extent of connective tissue remodeling. The ECM is a protein network that consists of either an interstitial, collagen-rich, ground substance housing the stromal–interstitial cells, or the basement membrane underlying epithelial and stromal cells. Each has a characteristic composition that determines the type of MMP responsible for its degradation. For example, MMP-1, previously known as tissue collagenase, breaks down interstitial ECM, whereas MMP-2 and -9, which are gelatinases, are specific for the basement membrane ECM, which contains collagen IV, laminin, and fibronectin. The MMPs are neutral zinc proteinases that are secreted as latent zymogens requiring proteolysis for activation. The *in vivo* mechanisms of activation are not known but are thought to involve specific proteases, including plasmin and some of the MMPs themselves and an interaction with growth factors and cytokines such as tumor necrosis factor α (TNF-α), EGF, basic fibroblast growth factor (bFGF), TGF-β and interleukin-1 (IL-1), which are often found in association with the ECM.

The MMPs required for degrading interstitial and basement membrane ECM, and their inhibitors, can be found in the uterus and the ovary. Potential functions of MMPs in the uterus include angiogenesis, implantation, endometrial remodeling and menstruation, activation of growth factors such as FGF and the colony-stimulating factors (CSF) by releasing them from the ECM, preparation of the cervix for birth, and collagenolysis in the myometrium after birth. In the ovary, the process of ovulation requires breakdown by MMPs of both interstitial (by MMP-1) and basement membrane ECM (by MMP-2 and MMP-9) to allow release of the egg from the follicle. MMPs are also likely to be involved in the extensive angiogenesis and tissue remodeling that accompanies the formation of the corpus luteum from the recently ruptured follicle.

3 Pathophysiological Considerations

3.1 Genetic Defects

A number of genetic defects have been identified, which have helped to define the role of several hormones and pathways

in the female reproductive system. Some examples are given in this section.

Pulsatile GnRH from the hypothalamus acts on the GnRH receptor on the pituitary gonadotropes to regulate gonadotropin gene synthesis, hormone synthesis, and secretion. Any mutations that affect the proper functioning of this hypothalamic-pituitary axis will therefore impinge upon the reproductive physiology of the individuals concerned. Two known genetic diseases have the phenotype of loss of GnRH gene expression. The *hpg* mouse is infertile as a result of a lack of GnRH secretion from the hypothalamus due to the deletion of the GnRH gene. Transgenic insertion of a normal GnRH gene can restore reproductive function in these mice. In humans, however, individuals exhibiting a similar phenotype, hypogonadotropic hypogonadism, have impaired GnRH secretion despite having a normal GnRH gene. These individuals possess mutations that affect other genes that are important in the various levels of GnRH expression, synthesis, and actions. For example, individuals with Kallman's syndrome have infertility, which is associated with anosmia. The defect in Kallman's patients is due to an X-linked defect that arrests the migration of GnRH neurons from the olfactory placode to the hypothalamus during fetal development, such that in the adult there are no GnRH neurons in the hypothalamus. The *KAL* gene is located at Xp22.3 and encodes a neural adhesion molecule with structural similarities to neural cell adhesion molecule (NCAM). Mutations in the genes that are important for transcription factors (such as SF-1, Dax) and for gonadotrope development, GnRH biosynthesis (*PC-1* mutations causing abnormal processing of GnRH), or function (GnRHR mutation affecting GnRH action at the receptor level), cause varying degrees of hypogonadotropic hypogonadism. Interestingly, specific mutations of the human GnRH gene have not been found.

The gonadotropins, LH and FSH, are heterodimeric hormones containing a common α-subunit noncovalently bound to a hormone-specific β-subunit. Women with either homozygous or heterozygous mutations in the *FSH*β gene have delayed puberty and primary amenorrhea. Although serum FSH was not detectable, serum LH was elevated, and treatment with exogenous FSH restores folliculogenesis, ovulation, and fertility, confirming the importance of FSH in antral development and granulosa cell steroidogenesis.

In familial male precocious puberty, an autosomal dominant, male-limited, gonadotropin-independent disorder, affected males begin puberty as young as age 4. The genetic defect leading to this syndrome has been shown to be due to a single base change in the LH receptor that results in an amino acid substitution in the sixth transmembrane domain, which in turn leads to constitutive activation of the receptor. Thus, cyclic AMP production is increased in the absence of LH, triggering Leydig cell activity and testosterone production. A similar syndrome is testotoxicosis, which also results in precocious puberty. The defect in this case is in the LH receptor linked G-protein Gsα, which activates adenylyl cyclase. A single base mutation again results in an amino acid substitution, causing constitutively activated Gsα, which elevates adenylyl cyclase and thus cAMP in the testis. This mutation, however, also results in resistance to hormones that activate cAMP (parathyroid hormone and TSH), and these two disparate effects are attributed to the mutated Gsα protein, which is unstable at 37 °C but retains function at the lower temperature of the testis. Both these syndromes

show a male-limited pattern of inheritance, probably because LH is sufficient to trigger production of testosterone in males, but both LH and FSH are necessary to trigger steroidogenesis in the ovary. Thus, constitutive activation of the LH receptor alone would not be sufficient to trigger precocious puberty in females.

McCune–Albright syndrome is characterized by polyostotic fibrous dysplasia, café au lait pigmentation of the skin, and multiple endocrinopathies, including precocious sexual development. The genetic defect in this syndrome is an activating mutation in the Gsα protein. This syndrome exhibits sporadic occurrence and is believed to be due to a dominant somatic mutation that occurs early in development, resulting in precocious puberty in both males and females, with females having luteinized follicular cells in the ovary at a very young age.

The importance of estrogen for normal development has been demonstrated in patients with genetic defects in the gene for P450arom, the key enzyme that catalyzes the conversion of testosterone to estradiol, androstenedione to estrone, and 16α-hydroxylated dehydroepiandrosterone to estriol. In females, absence of estrogen gives rise to ambiguous genitalia, and patients have hypergonadotropic hypogonadism at puberty, fail to develop secondary sexual characteristics, and exhibit progressive virilization. This demonstrates that estrogen is essential in the female for normal development of secondary sexual characteristics, including a pubertal growth spurt. Affected males have normal male sexual differentiation and pubertal maturation, but are tall with eunuchoid proportions. They exhibit continued linear growth into adulthood, and have unfused epiphysis, and osteoporosis due to estrogen deficiency. Although estrogen was shown to be essential for normal sperm production and function in mice, its role in fertility is not clear in men. These cases demonstrate that estrogen is important in both sexes for normal skeletal growth and development, and are supported by studies of transgenic mice lacking the *P450arom* gene.

3.2 FSH Isoforms and Infertility

There is now substantial data showing that pituitary and serum LH and FSH exist as structurally heterogeneous isoforms, and not as uniform structures. Variation in carbohydrate structure, particularly sialic acid content, accounts for most of this heterogeneity. Other factors (e.g. sulfation, phosphorylation, other modifications to the carbohydrate structure) are possible.

The population of isoforms can change according to the sex and endocrine status of the animal, involving mechanisms that are not understood. For example, human pituitary FSH isoforms are either larger and/or more acidic, with a longer half-life in the male than in the female. The physiological significance of changes in the relative proportions of FSH isoforms is more readily understood in terms of their differences in clearance rates than any difference in their intrinsic (in vitro) biological activity. It is not clear whether differences in the isoform profiles of gonadotropins in individuals are reflected in the subjects' fertility or infertility.

3.3 Reproductive Tumors and Inhibin

After the isolation and characterization of inhibin and development of radioimmunoassays, there have been several reports of elevated levels of inhibin

immunoactivity in the serum of patients with granulosa cell tumors of the ovary. Because inhibin is normally undetectable in the serum of postmenopausal women, the potential value of the peptide as a tumor marker is particularly significant in women without endogenous ovarian function. A number of studies have now indicated that in women with granulosa cell tumors, all forms of inhibin are increased, with the increase in either total serum inhibins or inhibin B being the most consistently elevated. While total serum immunoreactive inhibin is elevated in 100% of patients with granulosa cell tumors, inhibin B is elevated only in 89 to 100% of cases, and pro α-C in 90%, with inhibin A showing the greatest variability in their predictive value. Total serum immunoreactive inhibin is elevated in more than 80% of postmenopausal patients with mucinous carcinomas of the ovary, in 17% of patients with serous carcinomas, and in 17% of patients with clear cell carcinomas of the ovary. The nature of the inhibin product appears to vary with the type of tumor. Serum FSH levels vary inversely with inhibin levels in granulosa tumors, consistent with production of biologically active, dimeric inhibin. In mucinous tumors, on the other hand, FSH levels were generally high despite elevated inhibin, raising the possibility that in these tumors, the biologically inactive inhibin α-subunit precursor is the major product. Alternatively, the mucinous tumors may overproduce activin, a dimer of the β-subunits, which has FSH-stimulating activity. These data also suggest that expression of the three inhibin genes, α, β_A, and β_B, and the subsequent posttranslational processing and assembly of the subunits are regulated differently in the different tumors.

It is of interest in this regard that 70 of 71 transgenic mice with a deletion of the α-inhibin gene developed gonadal tumors, leading the authors to conclude that the inhibin α may be a tumor suppressor gene. An alternative hypothesis is that in the absence of inhibin α, activin is over-expressed and could be the agent responsible for tumor development. Whatever the explanation, the data are difficult to reconcile with the reports of elevated inhibin levels in patients with ovarian cancer, necessitating new concepts regarding the pathogenesis of ovarian tumors and their treatment.

Inhibin is also a product of the placenta, leading to the suggestion that it may be a useful marker of trophoblastic diseases, particularly hydatidiform mole, as an adjunct to the measurement of intact chorionic gonadotropin. Preliminary data support the potential of inhibin measurements for detecting molar pregnancies, where levels are elevated in comparison to those at the appropriate stage of normal pregnancy, but more data are needed.

4 Perspectives

Significant advances have been made in our understanding of the regulation of the female reproductive system in recent years, primarily in the areas of autocrine and paracrine regulation, and in the receptor and second-messenger systems, which subserve the actions of hormones and local regulators. Nevertheless, caution should be exercised in interpreting the available information. The existence of some of the putative local regulators is based on the detection of expression of the mRNA and protein *in situ* or *in vitro*. Their production and physiological role *in vivo* is less certain in many cases. Attempts to rectify this deficiency (e.g.

by using mice with gene deletions) have not always provided a clear indication of physiological roles, partly because of the possible substitution or compensation of one regulator for another in these circumstances.

The second-messenger systems that serve the pleiotropic actions of many of the hormones and regulators are not well understood, particularly where one hormone can have multiple effects on the same cell. There is still much to be learned about the transcription factors that link the hormone action to the gene and the mechanisms by which these factors regulate the genes. We now know from the example of the TGF-β receptors that association of different receptor subtypes can lead to different affinities for the ligands, which is another point at which regulation could occur. Until recently, there has been a tendency to overlook the importance of binding proteins and metabolizing enzymes in determining the local concentrations of *biologically active* hormones or factors; the molecular mechanisms controlling these substances are now under active investigation.

In addition to the reservations just noted, there are a number of key processes in the female reproductive system that we still do not understand. They include the following:

- The nature and regulation of the GnRH pulse generator
- The balance between endocrine and paracrine regulation of cells
- Control of reinitiation of growth and atresia of ovarian follicles
- Mechanisms controlling menstruation and implantation
- Immune responses to pregnancy.

Molecular approaches will play a major part in solving these inadequacies.

Flow Cytometry

Cell Sorting

A flow cytometer measures between one and thirteen or more parameters on single cells. The flow system is used to deliver cells to the point of measurement. In most instruments, the cells are interrogated by laser light. Measurements are made of scattered light and of fluorescence, either from the cells or, more commonly, from labelled probes. Sub-populations of cells may also be physically sorted for further study. The article briefly describes the main attributes of the technology and its applications in clinical areas and in mammalian biology.

1 Introduction

Flow cytometry is widely used in fields as diverse as immunology, hematology, cell biology, marine biology, and microbiology. As its name implies, it is a technique for measuring cells in a flow system. Its most important features are that it makes measurements on single cells, it records between 2 and 13 parameters per cell depending on the instrument, and it can measure thousands of cells a second. These features enable the analysis of subpopulations, in particular, subsets with a frequency as low as 1 in 10^4 can be enumerated. Additionally, some instruments are capable of sorting subpopulations of cells with a purity of 99%. In addition to cells, other particles, such as nuclei, chromosomes or small beads, can also be studied.

The disadvantage of the technique is that it requires a suspension of single cells, which can be difficult to obtain from solid tissues, and, while the flow cytometer can measure the amount of an entity in a cell, it cannot measure its intracellular distribution.

I have previously published a succinct description of flow cytometry and its applications. Other, longer, introductory books as well as books that describe protocols for many applications of flow cytometry are also available.

2 The Instrument

2.1 The Flow Chamber

The flow chamber lies at the heart of the instrument. In it, cells are injected into a stream of either water or saline solution (called the *sheath fluid*). The sample stream is thereby hydrodynamically focused so that single cells are delivered to a defined point at which a light beam is focused (Fig. 1). The light source is usually a laser, although some, mainly older instruments, use an arc lamp. As cells pass through the laser beam, they will scatter light and may also fluoresce. While strong autofluorescence may be observed in some cells, particularly marine algae, cells are usually labeled with one or more of a variety of fluorescent markers.

Most instruments will collect light scattered by the cells in a narrow angle in a forward direction (forward scattered light, FS) and also light scattered at right angles to the laser beam (side scatter, SS). Fluorescences are collected and separated by optical filters into different wavelengths. Typically, four fluorescent parameters can be acquired, although in some instruments, this can be as many as eleven.

There are two basic designs of flow chamber in general use; the cuvette flow chamber and the ''jet-in-air'' or ''stream-in-air.'' The latter is only used in instruments that can physically sort cells (see Sect. 3.4 below).

In the cuvette chamber, the interrogation point, at which the laser beam is focused on the sample, is inside the chamber (Fig. 1). In an analyzer, the sheath and sample streams are taken to waste in a fully enclosed system; in a cell sorter, the stream emerges into the open air. In a ''stream-in-air'' chamber, the interrogation point is immediately outside the chamber. While this system has advantages for cell sorting, it has inferior optical properties. The airstream interface scatters light, which has to be partially blocked by an additional obscuration bar fitted in front of the lens used

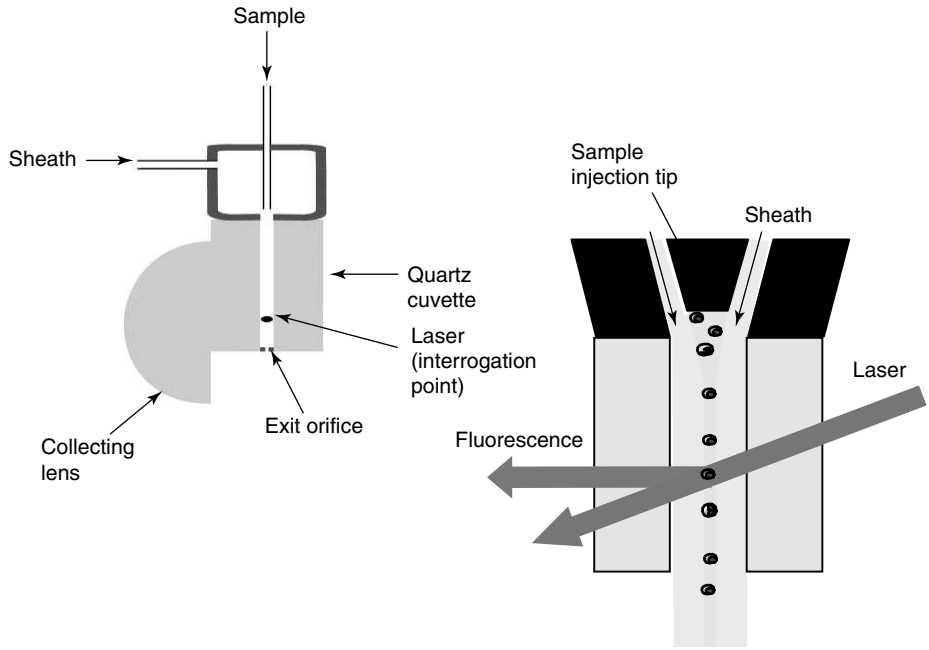

Fig. 1 Diagrammatic representation of a flow chamber. (See color plate p. xxiv.)

to collect fluorescent light at right angles to the laser beam. Because it is less efficient, it requires a laser of higher power.

2.2 Fluidics

The sheath fluid is normally forced through the flow chamber under pressure. The sample is usually injected into the sheath stream by applying a difference in pressure between sample and sheath fluid containers. The difference will control the volume flow rate of the sample. Alternatively, it may be injected into the stream using a motor connected to the piston of a syringe. The flow rate of the sample is then controlled by changing the speed of the motor. With this arrangement, a predefined volume of sample can be used, which enables absolute cell counting.

2.3 Light Source

Lasers are the preferred light source because they produce a single wavelength of high intensity. Nearly all instruments are fitted with an argon-ion laser, which gives blue light at 488 nm – a convenient wavelength for exciting the commonly used fluorochrome, fluorescein. Bench-top instruments are usually fitted with an air-cooled laser producing about 15-mW power. ''Stream-in-air'' sorters need more powerful lasers, frequently water-cooled, which have the advantage that they can, if required, be tuned to other wavelengths.

A second or third laser may be fitted so that cells can be excited at more than one wavelength. The choice depends on the applications; often a He–Ne laser giving red light at 630 nm is installed. A third laser will be selected to give UV, for

example, a He–Cd laser with an output at 325 nm. A wide range of solid state lasers are now available giving light at, for example, 405, 488, 530, or 635 nm.

2.4 Optics

The optical layout of typical flow cytometer is shown in Fig. 2.

Laser light is focused onto the point of measurement by a lens or lenses generally designed to give an elliptical laser spot. A blocker, or an obscuration bar is fitted behind the flow cell to block the laser beam. A light detector (such as a PIN diode) is positioned behind the obscuration bar to detect light scattered over a narrow angle in the forward direction.

Fluorescent and scattered light is collected at right angles to the laser beam and focused onto a series of photomultipliers (PMTs). Light of different wavelengths is selected using a series of dichroic and barrier (bandpass) optical filters. In the arrangement shown in Fig. 2, the dichroic filters are long pass filters, that is, they reflect light below a certain wavelength and pass light above that wavelength.

2.5 Signal Processing

Until recently, the signals from the PMTs were amplified and processed electronically before passing through analog-to-digital (ADC) converters, the digital signals being passed to a computer for data analysis. The trend now is to convert at an early stage and to manipulate the signals digitally. Using analog electronics, the signal is amplified in either a linear or logarithmic amplifier; using digital electronics, the amplified signal is presented on either a linear or a logarithmic scale. The signal may also be processed to output the width of the signal generated on the PMT, its height or the total integrated signal (area).

A threshold is set on the output voltage of one (or possibly two) of the measured parameters so that only signals above a certain limit are processed; this is sometimes referred to as the discriminator setting. The threshold, which is set by

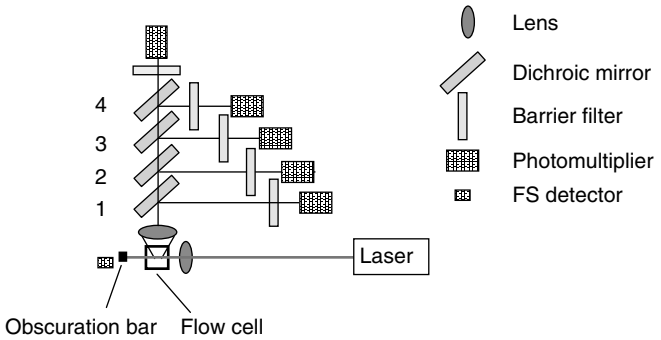

Fig. 2 The optical layout of a typical flow cytometer. Using an argon-ion laser emitting light at 488 nm, the optical components could be as follows: (1) Dichroic selecting light <500 nm; blue bandpass (488 nm). (2) Dichroic selecting light <540 nm; green bandpass (520 nm). (3) Dichroic selecting light <595 nm; orange bandpass (575 nm). (4) Dichroic selecting light <640 nm; red bandpass (620 nm) Final filter: long pass >650 nm. (See color plate p. xxiv.)

the operator, ensures that the instrument processes signals from cells (or other particles under study) and not from small debris or noise in the system.

3 Measurement

3.1 Light Scatter

Light scattered by particles as they pass through the laser beam is measured over a narrow angle in a forward direction (forward angle light scatter, FS) and also at right angles to the laser beam (side scatter, SS). The intensity of scatter is proportional to the size, shape and optical homogeneity of cells (or other particles); it is strongly dependent on the angle over which it is measured. Forward scatter may show variation between different flow cytometers reflecting the different geometry of the instruments.

Forward scatter tends to be more sensitive to the size and surface properties and can be used to distinguish live from dead cells while side scatter tends to be more sensitive to inclusions within cells and can be used to distinguish granulated from nongranulated cells.

3.2 Fluorescence

In instruments fitted with a laser giving blue light at 488 nm, the filter set will usually be selected to observe fluorescence from fluorescein (512 nm), phycoerythrin (PE) (560 nm) and either phycoerythrin-cyanine5 (PC5, 670 nm) or peridinin-chlorophyll (PerCP, 675 nm), these being the fluorochromes most frequently used for immunofluorescence work. In instruments with more than one laser and more detectors, up to 11 different fluorescences can be measured. There is a wide range of other fluorescent probes available (see, for example, the Molecular Probes catalogue). They are usually selected for use with one of the standard optical filters; for certain probes, specific filter sets may be required.

Most fluorochromes emit light over a wide spectral range. Consequently, light from one fluorochrome will be detected on more than one PMT. For example, light from fluorescein is selected using a green filter and from PE using an orange filter. However, the emission from fluorescein has an orange component, which will give a signal on the PE detector. This spectral overlap can confuse the interpretation of the data and has to be corrected. The compensation parameters can either be set up in the instrument, so that compensated data is recorded, or the data can be compensated post-analysis using software. While electronic compensation is adequate if up to four fluorescent parameters are being measured, compensation for larger numbers of fluorescent parameters is best handled digitally, either in real time or off-line.

3.3 Data Processing

Because of the large number of parameters collected on, perhaps, 20 000 cells, it is difficult to visualize correlations between the parameters. The strategy adopted for the analysis of multiparameter data is to use ''gating.'' Two parameters are displayed in a correlated dot plot (often called a *cytogram*). A region is generated around a cluster of cells of interest; this region acts as a ''gate.'' Another cytogram is generated from two other parameters and the computer is instructed to display

only those events that fall in the gate set on the first cytogram (see Fig. 3).

3.4 Cell Sorting

Some flow cytometers are able to sort selected subsets of cells. There are two types of cell sorters, piezo-electric and charged droplet.

The piezo-electric sorters separate cells mechanically. When a desired cell is detected, voltage is applied to a piezo-electric device, which deflects the cell into a collecting chamber. These sorters are relatively inexpensive, simple to operate

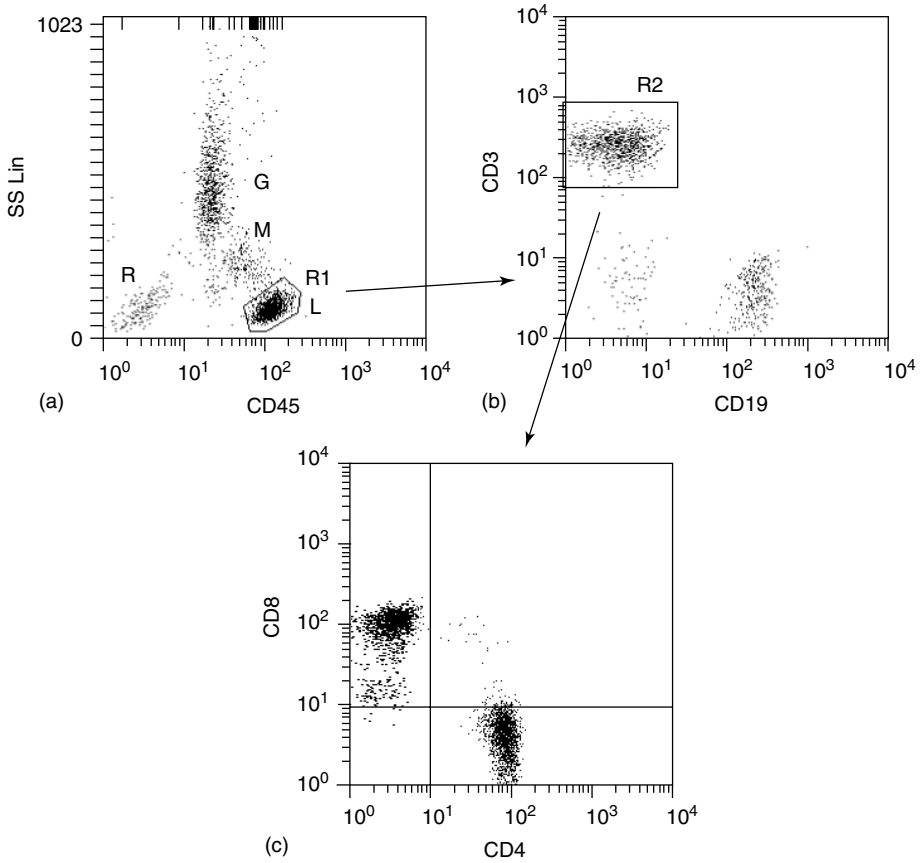

Fig. 3 Display of typical flow cytometric data. Peripheral blood leucocytes were labeled with antibodies to the cell surface antigens, CD3 (labeled with PE-cyanine5), CD4 (PE), CD8 (PE-Texas Red) and CD45 (fluorescein). (a) Initially, a cytogram of side scatter versus the pan leucocyte marker, CD45, was generated. Four clusters of cells are evident, cluster G is from granulocytes, M from monocytes, L from lymphocytes and R from residual red cells. A region (R1) was drawn around the lymphocytes. This was used as a gate set on subsequent cytograms. (b) Shows a cytogram of CD3 versus CD19 fluorescence of the lymphocytes only, identifying the T cells and B cells respectively. (c) Cytogram C has been gated on R1 and R2 and shows the T-cell subsets identified by CD4 and CD8. Data recorded on a Beckman Coulter XL using an argon-ion laser at 488 nm.

and slow (maximum sort rate is 300 cells s^{-1}). The sorted sample is always highly diluted, being mixed with a large amount of sheath fluid.

In charged droplet cell sorting, the stream from the flow cell emerges into the open air. The sheath fluid contains saline so that it is conductive. The flow cell is vibrated by a piezo-electric device, typically at 30 Hz, breaking the stream into well-defined droplets. When a cell to be sorted is in the next droplet to

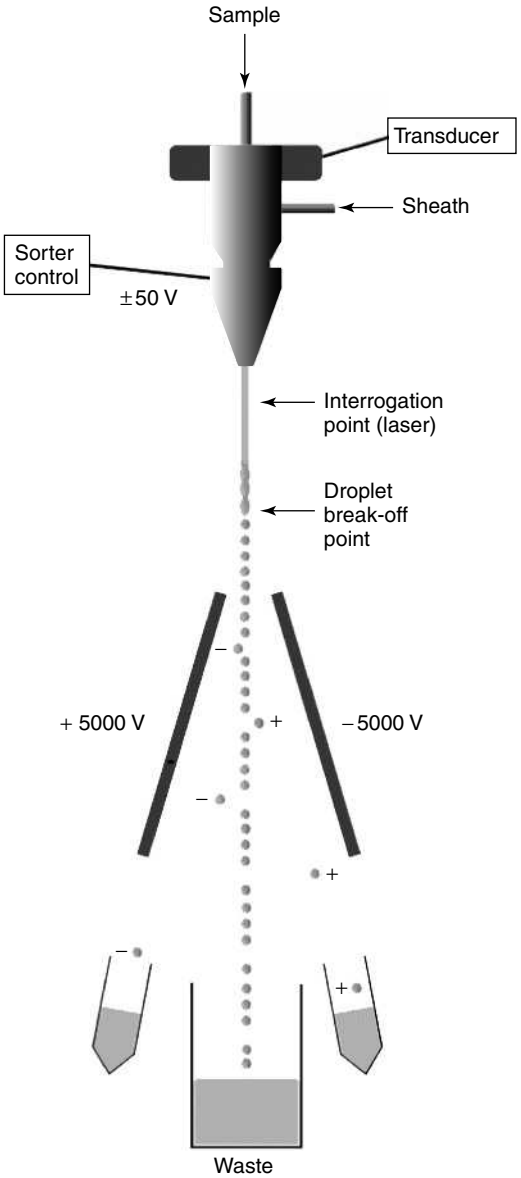

Fig. 4 A droplet deflection cell sorter.

be formed, the flow cell and stream is momentarily charged, thereby charging that droplet. The droplets pass through a pair of high voltage plates, charged droplets being deflected into the collecting vessels (Fig. 4).

The sorter has to be calibrated so that delay time between the cell passing through the laser beam (and being analyzed) and a droplet being formed is known to the computer, which will trigger the charge pulse at the appropriate moment. The conditions must be stable throughout the sort so that droplet delay time does not change. On modern machines, the instrument can monitor the position of the droplet break-off and automatically correct any minor variation.

The original charged droplet cell sorters could sort cells at speeds up to 5000 cells s^{-1}. The modern instruments sort at, at least, 15 000 cells s^{-1}; some machines can run at 50 000 cells s^{-1}. Despite the increase in speed, flow cytometric cell sorters give a low yield compared to bulk methods, such as immunomagnetic separation. If the concentration of the subpopulation to be sorted is 10%, at a flow rate of 10 000 cells s^{-1} and allowing for some losses through rejection of coincidences, the maximum number of cells collected will be about 3.10^6 h^{-1}. The major advantage is that the purity is high (>98%) and the sort decision can be based on a multiparametric analysis so that small subpopulations can be purified.

4
General Applications of Flow Cytometry

There are a wide variety of applications of flow cytometry in most aspects of cell biology. Table 1 lists the most important.

Monitoring electropermeabilization
Gene tracking using fluorescent proteins
Microbead assays

4.1
Immunofluorescence

This is the most widespread application of the technology. Any protein associated with a cell can be measured if a suitable antibody is available and if there are sufficient molecules present. The most commonly measured proteins, particularly in clinical laboratories, are those associated with leucocyte differentiation, the so-called, CD antigens, most of which are found on the surface of cells.

After fixing or permeabilizing cells, intracellular proteins can also be measured.

A variety of companies supply antibodies to most of the antigens of interest in routine clinical applications and for clinical and biological research. These antibodies are supplied labeled with different fluorochromes so that combinations can be selected to allow the simultaneous measurement of several proteins. Multicolor immunophenotypic analysis can reveal new, previously unrecognized, subsets of cells giving new insights into immunology and into the pathogenesis of diseases of the immune system, including cancer.

Fluorescence resonance energy transfer (FRET) is used in several applications in flow cytometry. If two fluorophores are sufficiently close to one another, energy may be transferred from one to the other. New fluorochromes for immunofluorescence have been made utilizing this principle. For example, if a conjugate of cyanine 5 and phycoerythrin (PE) is exposed to blue light, the PE will absorb the light, pass its energy to the cyanine, which fluoresces. The fluorescence is shifted from orange (PE alone) to red (cyanine 5). The principle can be applied to observe the interaction of two proteins on the surface of cells. Antibody to one protein is labeled with a donor dye, antibody to the other with an acceptor dye. When the proteins come into close contact, the fluorescence of the donor decreases while that of the acceptor increases.

4.2 Measurement of DNA

Measurement of the DNA content of cells gives information about the DNA ploidy and the cell cycle. There are several compounds whose fluorescence increases on binding to DNA and which bind stoichiometrically. The most commonly used of these is propidium iodide (PI), which is excited by blue light and fluoresces red.

Examples of DNA histograms are shown in Fig. 5. In order to estimate the percentage of cells in the G0/G1, S, and G2/M phases of the cell cycle, the overlap between G1 and early S and between G2 and late S has to be resolved. This is generally accomplished by a computer program that attempts to model the DNA histogram.

DNA measurement can be combined with immunofluorescence measurements (Fig. 6). If several immunofluorescent parameters are to be measured, PI may cause a problem because its fluorescence

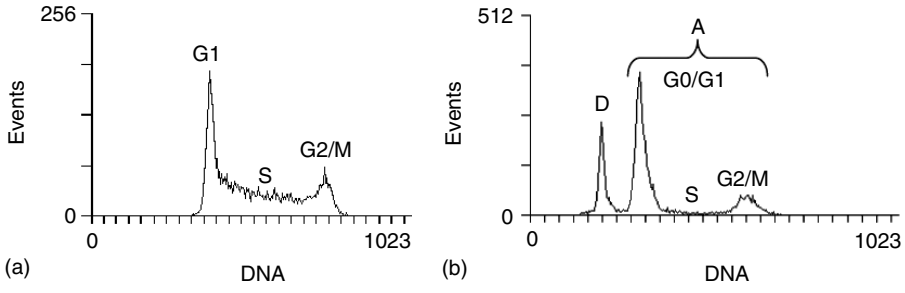

Fig. 5 DNA histograms. (a) Murine leukemic cell line. Cells were fixed in 70% ethanol, suspended in phosphate-buffered saline and stained with PI. The phases of the cell cycle are labeled. (b) Nuclei extracted from a formalin-fixed, paraffin-embedded biopsy of a breast carcinoma. D, diploid cells; A, aneuploid tumor cells, with the phases of the cell cycle labeled. Data recorded on a Beckman Coulter Elite using an argon-ion laser at 488 nm.

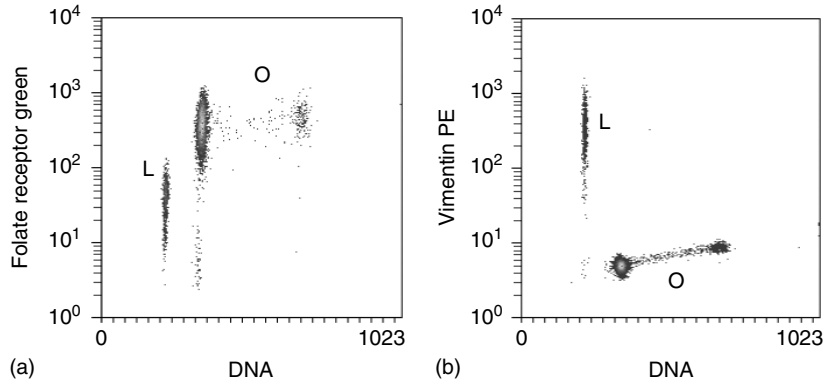

Fig. 6 Immunofluorescence and DNA measurement combined. Ascitic cells from a patient with ovarian carcinoma. The cells were labeled with anti-folate receptor-FITC, anti-vimentin-PE and PI. Note that there are both diploid and aneuploid cells present. (a) The diploid cells are leucocytes, which express vimentin (b) while the vimentin-negative ovarian carcinoma cells express folate receptor. Data, supplied by Willem Corver, University of Leiden, was recorded on a BD FACScan using an argon-ion laser at 488 nm.

spectrum overlaps strongly with commonly used fluorochromes, such as phycoerythrin and phycoerythrin-cyanine 5. Depending on which lasers are available, alternative dyes are often used; for example, a *bis*-benzimadazole, such as Hoechst 33342, which is excited by UV to give blue fluorescence, or the anthraquinone, DRAQ5, which fluoresces a deep red (700 nm).

4.3 Other Flow Cytometric Methods

4.3.1 Measuring Enzyme Kinetics

An enzyme substrate can be linked to a fluorescent molecule to give a nonfluorescent compound. The action of the enzyme will release the substrate leaving a fluorescent compound. Fluorophores, which have been used in this application, include fluorescein and rhodamine 110. Generally, this method will only give a crude estimate of enzyme activity since the kinetics of the reaction can be affected by the rate of diffusion of the complex into the cell, the rate of diffusion of the fluorophore out the cell and the released substrate out of the cell, and compartmentalization within the cell.

This approach has been adapted to enable charged compounds to be loaded into cells. For example, the calcium indicator, indo-1, is loaded into the cell by incubation with the acetoxymethyl ester. In the cell, esterases remove the acetoxymethyl groups leaving the fluorescent indo-1, which, being charged, remains trapped in the cell.

4.3.2 Following Changes in Membrane Potential

There are several lipophilic dyes that partition between the cell and the surrounding medium according to the plasma membrane potential. Of particular use are a series of oxonol dyes which, depending on their substituents, have different wavelengths of excitation and emission.

Many cyanine dyes, such as dicyanine, 3′,3′-dihexyloxacarbocyanine have a

positive charge and are taken up by the mitochondria and the strength of their fluorescence within the cell reflects the mitochondrial membrane potential. One of the cyanine dyes, abbreviated to JC-1, exists as a green fluorescent monomer at low concentrations and at low membrane potential. At high concentrations or higher membrane potential, it forms red-fluorescent aggregates. The dye can be excited at 488 nm and changes in mitochondrial membrane potential can be followed by measuring the ratio between green and red fluorescence.

4.3.3 Intracellular Calcium Ions

Ca^{2+} has an important role in cell signaling. The calcium indicator, indo-1, which is excited by UV, has a fluorescence emission maximum of about 490 nm in the absence of Ca^{2+}; in the presence of 1 mM Ca^{2+}, the emission maximum is about 410 nm. Changes in the concentration of intracellular Ca^{2+} are recorded by observing fluorescence at 400 and 520 nm and measuring the ratio between the two fluorescences.

Other dyes, which are sensitive to Ca^{2+} and can be excited by blue light, are fluo-3 and Fura Red. Ca^{2+} concentration does not affect the emission wavelength, just the intensity of emission so that these indicators cannot be used to measure changes in Ca^{2+} on a cell-by-cell basis; only the overall changes in a population of cells.

4.3.4 Intracellular pH

There are several compounds that can be used to measure intracellular pH; the most useful is SemiNaphthoFluorescein (SNARF-1), usually used as the carboxy-derivative. Under acidic conditions, carboxy-SNARF-1 fluoresces yellow-orange (580 nm), under alkaline conditions, it fluoresces red (640 nm). The pK_a is about 7.5 at room temperature and the pH is measured by recording the ratio between the fluorescences at 580 and 640 nm.

4.3.5 Intracellular Glutathione

Glutathione has an important role in the cell in reacting with potential damaging oxidative species. Increased levels of glutathione may also be associated with resistance to some cytotoxic drugs.

One assay for glutathione is based on the activity of the enzyme, glutathione-*S*-transferase. Cells are incubated with the dye, monochlorobimane (MClB), which crosses the plasma membrane. In the cytoplasm, the enzyme catalyzes the reaction with glutathione yielding a fluorescent conjugate, which is trapped in the cell. MClB-glutathione fluoresces blue when excited by UV. MClB gives excellent results with rodent cells. It is less effective in human cells, which lack the necessary variant of glutathione-*S*-transferase. As an alternative, monobromobimane, which reacts directly with sulphydryl groups, can be used.

4.3.6 Measuring Oxidative Species

There are several compounds which, in their reduced form, are nonfluorescent but which generate a fluorescent compound upon oxidation. Such compounds include dihydrorhodamine 123, dihydroethidium, and 2′,7′-dihydrodichlorofluorescein (dichlorofluorescin, DCFH). Dihydrorhodamine 123 and dihydroethidium diffuse freely into cells. Upon oxidation, rhodamine 123 is concentrated in the mitochondria and fluoresces green, while ethidium binds to DNA and fluoresces red.

DCFH can be loaded into cells as an ester. After conversion to DCFH by intracellular esterases, oxidation will yield a fluorescent product, 2′,7′-dichlorofluorescein.

These compounds have been used to observe oxidative burst in neutrophils, changes in the concentration of oxidative products during apoptosis and the production of intracellular oxidative species by ionizing radiation.

5 Specific Fields of Application

5.1 Clinical

Flow cytometry is universally used to classify leukemias. Immunophenotyping in combination with flow cytometry is also used to measure minimal residual disease in leukemias (Fig. 7), for stem cell enumeration in bone marrow transplant patients, monitoring HIV infection, quantifying feto-maternal hemorrhage, characterizing immunodeficiency diseases, analyzing paroxysmal nocturnal hemoglobinuria, in transplantation medicine, and for counting platelets and measuring platelet activation. Other routine clinical applications include the detection of auto-antibodies and the enumeration of reticulocytes in blood (Fig. 8).

Applications in the field of clinical research include the measurement of intracellular cytokines, the study of phagocyte biology and function (including phagocytosis and oxidative burst during activation), measurement of cell–cell interactions, the measurement of cell-mediated cytotoxicity and the study of viral infection.

5.2 Long Term Labels for Cells

There are some fluorescent labels that will survive in cells for days, if not weeks. If the cells divide, the label will be carried over into the daughter cells. One of the several compounds used is carboxyfluorescein diacetate, succinimidyl ester (CFDA SE). The compound will diffuse into cells where the diacetate groups are cleaved, generating a fluorescent compound; the succinimidyl groups react with thiols in the cytoplasm, retaining the dye in the cell.

Applications include studying cell fusion or clustering, tracking cells *in vivo*, identifying one partner in the interaction between two types of cell (for, example, a cytotoxicity reaction), and following cell division.

Genes for naturally fluorescent proteins (such as green fluorescent protein, GFP) have been introduced onto the DNA of cultured cells, thereby rendering the cells fluorescent. The GFP gene can be introduced into a plasmid for use as a reported molecule after transfection. Transfected cells can be purified by cell sorting on the flow cytometer.

5.3 Measurement of Cell Proliferation

The study of cell proliferation is an important and powerful application of flow cytometry. One can, for example, derive information about the proliferative status of tumors, observe the effects of cytotoxic drugs on the cell cycle or study the proliferation of subsets of lymphocytes undergoing immune stimulation.

There are several different approaches that can be used. One can measure the cell cycle phases, the rate of movement of cells through the cell cycle, the division of

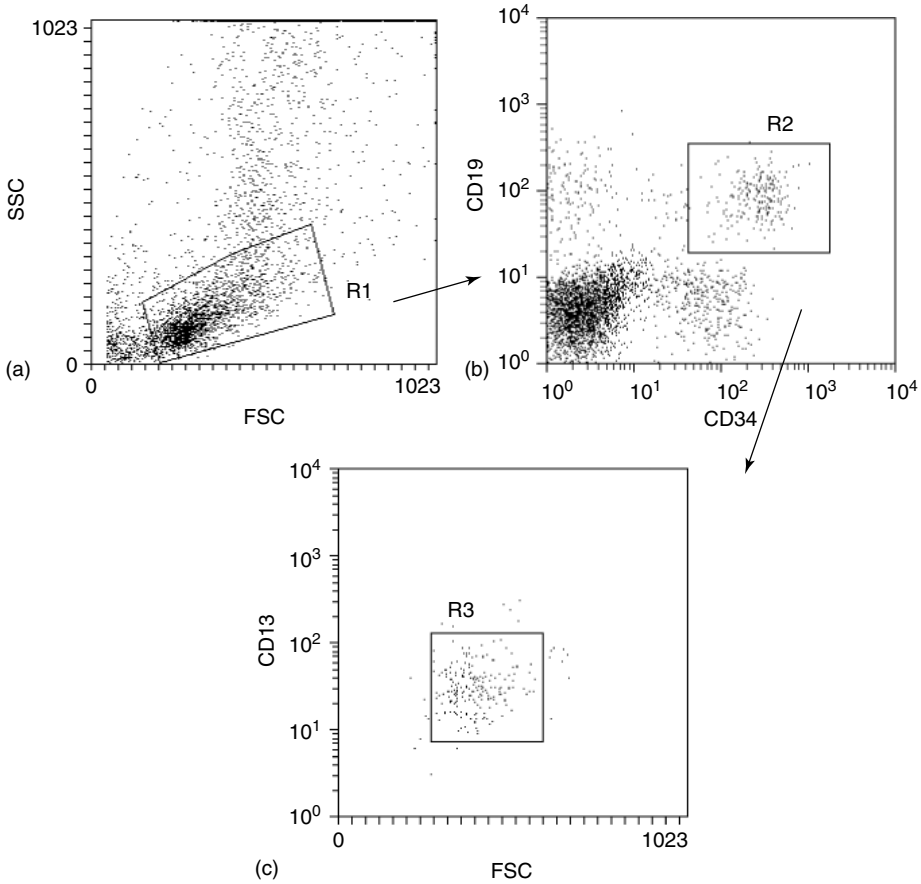

Fig. 7 Bone marrow sample obtained from a child with acute lymphoblastic leukemia undergoing treatment and considered to be in clinical and morphological remission. Mononucleated cells were separated on a density gradient and labeled with three antibodies associated with the phenotype of the leukemia - CD19/CD34/CD13. (a) Cytogram of light scatter with a region, R1, set on the lymphocytes and lymphoblastic cells. (b) Cytogram of CD19 versus CD34 expression, gated on R1. A region has been drawn around the positive cells. (c) Cytogram of CD13 versus forward scatter. Region, R3, has been drawn around the CD13 positive, tumor cells. There were 199 events in R3 out of a total of 10 000 events recorded. Data, supplied by Dario Campana, St. Jude's Hospital, Memphis, was recorded on a BD FACScan using an argon-ion laser at 488 nm.

label between daughter cells or observe the distribution of cell cycle–related proteins.

5.3.1 The DNA Histogram

A measurement of the DNA histogram should always form the basis of any study of changes in the proliferative state of cells. Some effects of chemotherapeutic drugs on the cell cycle are shown in Fig. 9.

5.3.2 Using BrdUrd/Anti-BrdUrd

If cells are pulse-labeled with 5-bromodeoxyuridine (BrdUrd), only cells in S-phase

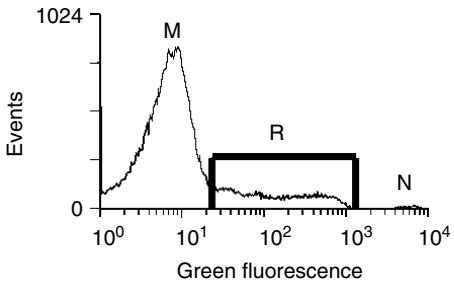

Fig. 8 Reticulocyte analysis. Histogram of green fluorescence from blood incubated with thiazole orange, which stains RNA and DNA. M, mature erythrocytes; R, reticulocytes; N, nucleated red cells. Data, supplied by Terry Hoy, University of Wales, Cardiff, was recorded on a BD FACScan using an argon-ion laser at 488 nm.

(b) 5 h after a 2-h incubation with a Pt(IV) dicarboxylate at $3 \times IC_{50}$. There was an accumulation of cells in S-phase (arrowed) caused by a slowdown in the movement of cells through S-phase. (c) As (b) but recorded after 24 h. The drug has caused a block in G2 and cells have accumulated in that phase of the cell cycle (arrowed). (d) HL60 cells 4 h after the addition of 10 μM camptothecin. S-phase was completely blocked; cells originally in G2 have divided and, as there was no movement of cells from S to G2, there is an absence of cells in G2 (arrowed). Other details as in Fig. 5.

will contain BrdUrd. During subsequent incubation of the cells, the BrdUrd-labeled cells will progress around the cell cycle. The progression can be followed by fixing the cells at different time intervals and visualizing the BrdUrd with an anti-BrdUrd antibody; PI is added to show the phases of the cell cycle (Fig. 10). If cells are incubated with a drug, irradiated or a growth factor is withdrawn immediately after labeling, the effects of the treatment on progression around the cell cycle can be followed. Alternatively, pulse-labeling after treatment of the cells would reveal the state of the S-phase cells (see Fig. 10).

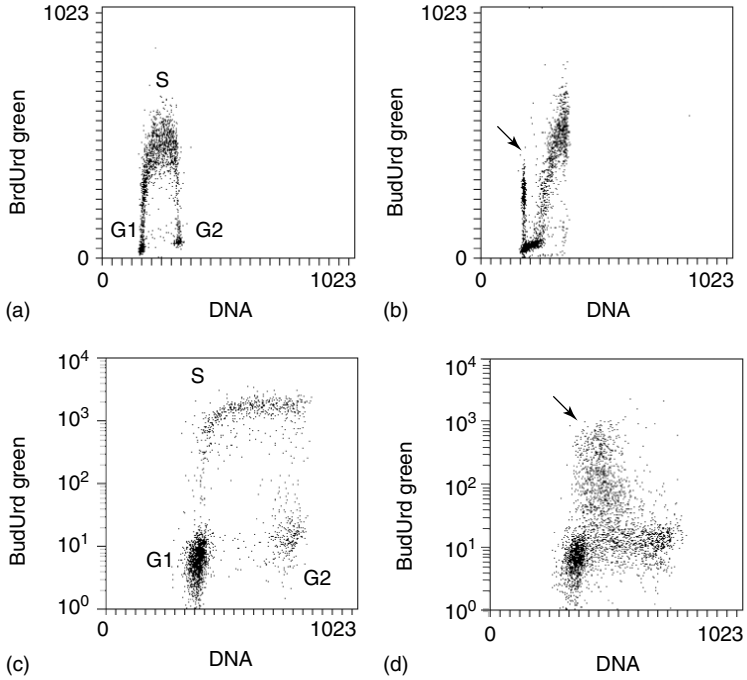

Fig. 10 Cytograms of green versus red (PI/DNA) fluorescence from cultured cells pulse-labeled with BrdUrd, fixed and labeled with anti-BrdUrd-FITC and PI. (a) & (b) Chinese hamster V79 cells, 0 (a) and 5 h (b) after pulse-labeling. At 5 h, the labeled cells had moved about halfway through the cell cycle. Cells in late S-phase at time 0 had divided and were in G1 (arrowed). Data supplied by George Wilson, Karmanos Cancer Institute, Detroit. (c) & (d) Neuroblastoma cell line 0 h after pulse-labeling. (c): no drug; (d): 24 h after a 2 h incubation with cisplatin. Note that in (d), there was a population of S-phase cells that were not synthesizing DNA. A further population were accumulated in early/mid S-phase and were synthesizing less DNA than the control (arrowed). All data recorded on BD FACScans using an argon-ion laser at 488 nm. Noted that a linear amplifier was used in (a) & (b) to record green fluorescence and a logarithmic amplifier for (c) & (d).

This method can be applied *in vivo*. BrdUrd has a half-life of about 20 min in an animal; a single incubation of BrdUrd is equivalent to a pulse label. Figure 11 shows nuclei from a rat mammary tumor. The rat was killed and the tumor removed 4 h after the injection of the BrdUrd. From the observed movement of the cells through S-phase during this time, the S-phase transit time can be calculated.

5.3.3 The BrdUrd-Hoechst/PI Method

The fluorescence of *bis*-benzimidazole dyes (Hoechst 33258 and Hoechst 33342) bound to DNA is quenched by BrdUrd. Consequently, continuous labeling with BrdUrd and subsequent staining of DNA with Hoechst 33258 separates cells according to the number of replications they underwent during the period of labeling. Addition of a DNA label unaffected by BrdUrd, such as PI, resolves the cell

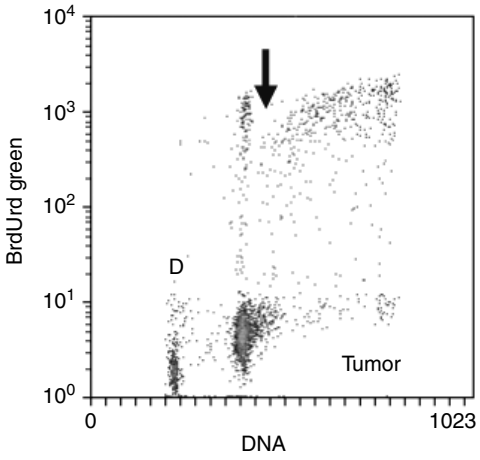

Fig. 11 Cytogram of green (anti-BrdUrd) fluorescence versus PI/DNA of a rat mammary tumor. The rat was injected with BrdUrd 4 h before the tumor was excised. The diploid cells are marked, D; the tumor was aneuploid. From the length of the "window" (arrowed) between G1 and the S-phase label, the time of S-phase can be calculated. Cells prepared by Tim Smith, Royal Marsden NHS Trust, Sutton, and the sample analyzed on a Coulter Elite by Jenny Titley with an argon-ion laser giving 200 mW at 488 nm.

cycle into the G0/G1, S and G2/M compartments. Hoechst 333258 is excited by UV, and the small number of machines equipped with a UV laser has limited the use of this technique. Now that two and three laser instruments with UV lasers are becoming more common, this method may find more widespread use.

5.3.4 Measuring Cell Proliferation through the Division of Label between Daughter Cells

Some labels will persist in cells for many days, if not weeks. Two compounds have been used for this application: carboxyfluorescein diacetate, succinimidyl ester (CFDA SE), and PKH26, an analog of acridine orange with an N-linked 26 carbon alkyl chain. CFDA SE diffuses into cells wherein it is converted to carboxyfluorescein, succinimidyl ester (CFSE); its reaction with amines stabilizes the fluorescent product in the cell. Because of its long alkyl side chain, PKH26 becomes anchored in the plasma membrane of cells.

To measure proliferation, the cells are labeled and their fluorescence recorded. After incubation under the appropriate experimental conditions, the fluorescence is rerecorded. The fluorescence from the cells that have divided once, twice, and so on, will have half, quarter the fluorescence of the undivided cells. Figure 12 shows data from murine T-cells in culture. After two days in the stimulated cultures, there are six peaks in the histogram of CFSE fluorescence; some of the cells had divided five times in 48 h, while other cells had not divided once.

5.4 Studying Cell Death

5.4.1 Necrosis

Assays for necrosis measure the integrity of the plasma membrane. There are several dyes that fluoresce on binding to DNA but are excluded from the cell by the plasma membrane, the most commonly used being PI. On addition of the dye, those cells with a damaged membrane show positive fluorescence.

An alternative approach is to load the cells with a fluorescent dye, for example, by incubation with carboxyfluorescein diacetate. When the plasma

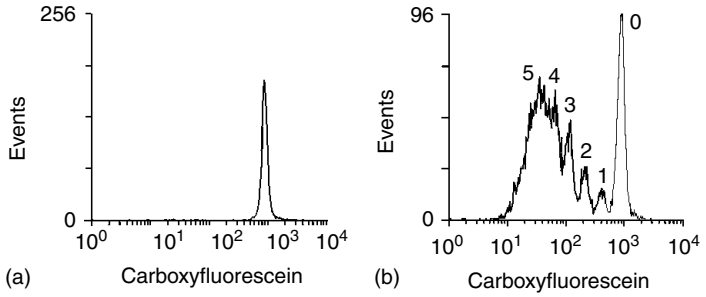

Fig. 12 Murine CD4+ cells in culture labeled with CFSE. The unstimulated cells (a) gave a single peak on the fluorescence histogram while the histograms from stimulated cells (b) exhibited multiple peaks due to dilution of the label during cell division. The numbers of cell divisions are marked on histogram (b). The cells were stimulated by incubating with antigen-presenting cells and an appropriate peptide. Data supplied by Maria Daly, GlaxoSmith Kline, and recorded on a Beckman Coulter XL with an argon-ion laser.

membrane is damaged, the dye is lost from the cell. The two assays can be combined.

5.4.2 Apoptosis

The application of flow cytometry in following the apoptotic cascade has been reviewed. The features that can be measured using flow cytometry include

- expression of proteins involved in the apoptotic cascade, including proteins generated during the cascade, such as activated caspases and cleaved poly (ADP-ribose) polymerase (PARP);
- activation of caspases;
- changes in the mitochondrial membrane potential;
- changes in other functional parameters, such as intracellular pH, calcium ions, glutathione, and oxidative species;
- changes in the plasma membrane;
- cell shrinkage;
- DNA degradation.

5.4.2.1 **Activation of Caspases** There are antibodies available, which are specific for the activated form of many caspases. Caspase activity may be observed directly by incubating cells with a compound made of a peptide, specific for one of the caspases, connected to a potentially fluorescent group. An active enzyme will release the fluorescent group. Typically, a compound such as DEVD-rhodamine 110 is used. An alternative form of the assay uses a fluorescently labeled enzyme inhibitor, which will be concentrated in those cells containing active enzyme.

5.4.2.2 **Mitochondrial Membrane Potential (MMP)** The collapse of the MMP is a central feature of the apoptotic cascade and flow cytometry is the main method used for monitoring the MMP. Several dyes, including rhodamine 123, 3,3′-dihexyloxacarbocyanine iodide and 5, 5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolylcarbocyanine iodide (JC-1), are concentrated in mitochondria due to difference in the membrane potential of the

mitochondria in relation to the cytoplasm. When the mitochondrial membrane potential collapses, the overall fluorescence is reduced. In the case of JC-1, this is accompanied by a shift in the fluorescence from red to green.

5.4.2.3 **Changes in the Plasma Membrane** During apoptosis, the distribution and packing of the lipids in the plasma membrane changes. The permeability of the plasma membrane is also increased. Phosphatidyl serine (PS), which is normally exposed on the internal face of the plasma membrane, moves to the exterior of the cell during apoptosis. This change can be detected using the recombinant protein, annexin V, which binds to PS. Annexin V is labeled with one of the common fluorochromes, such as fluorescein or PE. Annexin V staining can be combined with one or more immunofluorescence stains to determine the phenotype of the apoptotic cells. Frequently, PI is added to distinguish cells in secondary necrosis.

There are several DNA binding dyes that are excluded by normal cells but are taken up by apoptotic cells; these include the *bis*-benzimidazole, Hoechst 33342, ethidium bromide, 7-aminoactinomycin D (7-AAD) and the dicyanine, YO-PRO-1. Figure 13 shows an example using 7-AAD.

5.4.2.4 **DNA Degradation** Cleavage of DNA at the linkers between the nucleosomes is a late event in apoptosis, resulting in DNA oligomers of about 200 bp. There are two methods by which this effect may be used to visualize apoptotic cells.

If apoptotic cells are fixed in ethanol and then resuspended in buffer, the small fragments of DNA are extracted from the cell. Consequently, the apoptotic cells will have a lower DNA content than normal cells. This manifests itself as a ''sub-G1'' peak in the DNA histogram (Fig. 14).

For the Tdt-mediated dUTP nick end-labeling (TUNEL) assay, the cells are fixed in paraformaldehyde followed by ethanol. All the fragments of DNA are retained within the cell and are available for labeling by the enzyme, terminal deoxynucleotidyl transferase (Tdt). A variety of labels may be incorporated into the DNA at the sites of the strand breaks, such as FITC-dUrd, biotin-dUrd, BrdUrd, by adding the triphosphate derivative to the incubation mix. Biotin-dUrd is visualized by the addition of streptavidin-FITC and BrdUrd by anti-BrdUrd-FITC. PI is finally added to

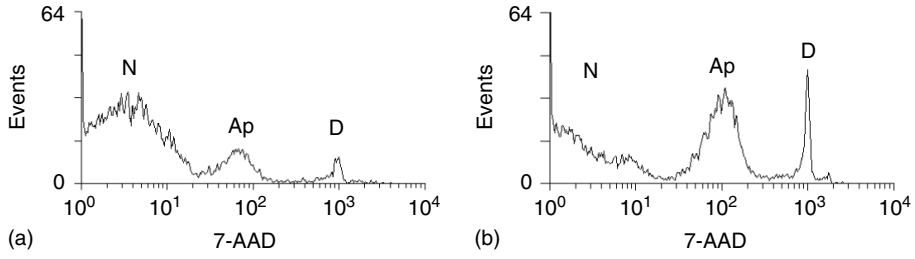

Fig. 13 Immature human thymocytes incubated with (a) dexamethasone for 0 h and (b) 24 h and then incubated with 7-AAD. The normal (N), apoptotic (Ap) and cells that had undergone secondary necrosis (D) are marked. Data, supplied by Ingrid Schmid, UCLA School of Medicine, was recorded on a BD FACScan using an argon-ion laser.

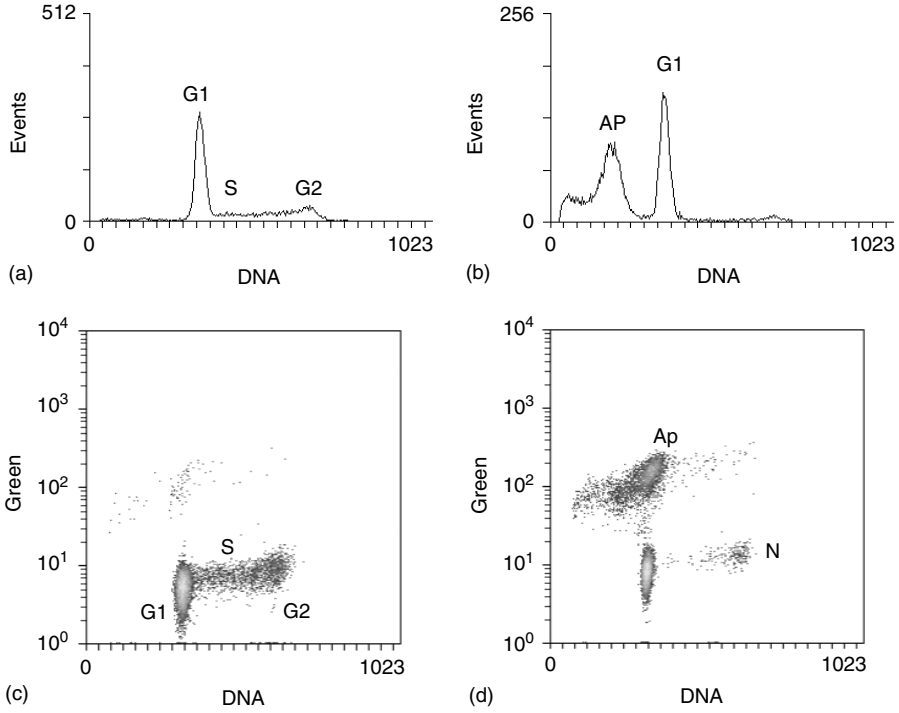

Fig. 14 Murine hemopoietic cell line that requires interleukin-3 (IL-3) for growth. (a) & (c): grown in the presence of IL-3; (b) & (d): after 16 h in the absence of IL-3. (a) & (b): DNA histograms. The sub-G1 peak from apoptotic cells is marked "Ap". (c) & (d): Cells labeled using the TUNEL assay. The cytograms of green fluorescence versus red (DNA/PI) fluorescence show the phases of the cell cycle and the negative, normal (N) and the positive, apoptotic cells (Ap). Simone Detre, Royal Marsden NHS Trust, London labeled cells for the TUNEL assay, Data recorded on a Beckman Coulter Elite using an argon-ion laser at 488 nm.

label the DNA. The position in the cell cycle from which apoptosis occurred is revealed as well as the percentage of apoptotic cells (Fig. 14).

5.5 Analyzing and Sorting Chromosomes

Sorting chromosomes requires a flow cytometer equipped with two large (5 W) argon-ion lasers and considerable expertise. A DNA stain of a suspension of chromosomes with a single dye (for example, PI) does not give enough resolution between the individual chromosomes. Two DNA stains are used – a *bis*-benzimidazole (Hoechst 33258) and chromomycin A3, each dye being excited by a separate laser. Hoechst 33258, excited by UV giving blue fluorescence, binds preferentially to AT-rich regions on the DNA; chromomycin A3, excited at 457 nm giving green fluorescence, binds preferentially to the GC-rich regions. The chromosomes can then be resolved on the basis of their total DNA content and their AT/GC ratio. All the individual chromosomes can be resolved with the exception of chromosomes 9–12, whose size and AT/GC ratios are not sufficiently separated.

5.6 Microbead Technology

Fluorescent microspheres (beads) offer a new emerging technology involving flow cytometry. A biomolecule can be attached to a bead and its interaction with other molecules studied; for example, the binding of two proteins; hybridization of DNA molecules; or the interaction of an enzyme with its substrate. Fluorescently labeled reporter molecules, such as antibodies, antigens, or nucleic acid probes can be used.

A particularly powerful application is the use of multiplexed arrays, for example, using two fluorescent dyes at eight different concentrations to give a set of 64 different beads. Each bead could carry a specific capture antibody; if the beads were fluorescent in the orange/red range, the detector antibodies might be labeled with fluorescein. Sixty-four assays could be carried out in the same tube simultaneously. The molecules measured might include hormones, cardiac markers, therapeutic drugs, drugs of abuse, and blood-borne viruses.

The same technology is being used for hybridization-based analyses for the detection of specific nucleic acid sequences.

Specific machines are being produced for these assays (for example, by Luminex Corporation).

6 Applications Other Than Mammalian Cell Biology

6.1 Microbiology

Generally, viruses are too small to be detected directly by flow cytometry but bacteria and other microorganizms, such as bacteria and yeasts, can be measured. Flow cytometric assays have been developed to determine features such as size, DNA content, surface receptors, membrane potential and intracellular pH.

One of the major applications has been in the study of antibiotic susceptibility. Flow cytometry is also being used to monitor water quality.

6.2 Marine Biology

The use of flow cytometry in monitoring the organisms in seawater is rapidly increasing. Many marine organizms are fluorescent and a combined measurement of light scatter and fluorescence at several wavelengths can yield a unique fingerprint for many organisms, such as the large variety of phytoplankton.

Instruments have been built to monitor seawater onboard a marine vessel and at fixed positions below sea level. Continuous monitoring has been achieved by mounting a small cytometer on a buoy and sending data to the mainland base by radio link (for example, Cytobuoy).

Keywords

Fluorescence Correlation Spectroscopy (FCS)
Monitoring of thermodynamic fluctuations of molecules via ultrasensitive detection of their emitted fluorescence.

Brownian Motion
The spatial consequence of thermodynamic fluctuations of particles in a macroscopic system, regarded as the origin of diffusion.

Single Molecule Detection
The ultrasensitivity of an instrument, allowing a detection of a single molecule.

Molecular Interactions
Interactions between compounds such as protein–protein, protein–DNA, ligand–receptor, and DNA–DNA, here studied by FCS.

Drug Screening
Search for new substances with therapeutic activity with the aim to develop them into new drugs.

In Fluorescence Correlation Spectroscopy (FCS), fluctuations of the fluorescence intensity of fluorophore-labeled molecules, excited by a sharply focused laser beam, are observed. Owing to high sensitivity, detection at the level of single molecules is possible. Thermodynamic fluctuations can thus be revealed, which would be difficult to detect at a macroscopic level. The technique can, in principle, offer information about any molecular dynamic process in the nanosecond time range and longer, manifesting itself as a change in fluorescence intensity without the need for any perturbation or synchronization of the system studied. The specific features of FCS make it a versatile tool for biomolecular studies, including determination of translational and rotational diffusion, concentration and density of molecules, chemical kinetics, and binding reactions. In this review, an overview of the theory and the typical experimental setup for FCS measurements will be given, along with some examples of how FCS can be used for molecular dynamic studies.

1 Introduction

In macroscopic systems at thermodynamic equilibrium, the concentrations of molecules of different species, and other parameters of the system, do not by definition, change with time. Various processes may take place, but because of the normally large number of molecules present in the system, they tend to cancel each other out. Therefore, the relative changes caused by the molecular processes are of a negligible magnitude on the macroscopic scale. However, if the number of molecules in the system is small, the processes do not average out to the same extent, and relative fluctuations in concentration, or any other parameter, can become significant. Since the fluctuations are governed by the molecular processes that take place in the system, analysis of signal fluctuations can provide a powerful way of investigating these processes. The fluctuations of a parameter, measured in a system in thermodynamic equilibrium, can be described by the same mathematical formalism that would be used in a relaxation experiment. However, unlike relaxation methods, where a macroscopic perturbation is applied in the form of temperature, electric field, or pressure jump, no external disturbance of the system is required for the fluctuation measurement.

The concept of number fluctuation analysis, in which the fluctuating number of particles within a fixed volume is analyzed in terms of its time dependence, has been introduced a long time ago. An early experimental application was that of Svedberg, in which the diffusion coefficients of colloidal particles were measured on the basis of theoretical analysis of Smoluchowski. In his analysis, Smoluchowski used the concentration autocorrelation function:

$$G_C(\tau) \equiv \langle C(t)C(t+\tau)\rangle = \langle \delta C(t)\delta C(t+\tau)\rangle + \langle C\rangle^2, \quad (1)$$

where the brackets denote the time average. The time-dependent part of this function expresses the typical time course of a fluctuation and its magnitude.

Different techniques have been developed that provide indications of number fluctuations: the dynamic light scattering technique, also known under the names quasi-elastic light scattering or photon correlation spectroscopy, exploits the light scattering intensity from the particles of interest. The electrical conductance of a solution can also be used as an indicator since it reflects the number and charges of the particles contained in the solution. Fluctuation analysis of electrical currents over sections of cellular or artificial membranes, known as Voltage Clamp, has been extensively used in the field of neurophysiology (with the later developed patch clamp technique as its single-molecule counterpart).

The utilization of fluorescence intensity as the fluctuating quantity was originally introduced by Magde, Elson, and Webb under the name Fluorescence Correlation Spectroscopy (FCS), and in a series of papers, they presented the theory and the first experimental realization of the technique. In the first FCS experiments, the average number of fluorescent molecules in the observation volume was about 10 000. However, thanks to the remarkable averaging power of the autocorrelation function, it was still possible to extract the motion of individual molecules from the large uncorrelated bulk fluorescence. In this respect, FCS is perhaps the oldest discipline of single-molecule fluorescence spectroscopy.

Although FCS showed great potential in a number of fields in the 1970s, it had not found a more widespread use until the last five to ten years. The reasons for the limited success of FCS at the initial stage were mainly related to high background light levels and to low detection quantum yields.

The situation was dramatically changed by the introduction of extremely small observation volumes in FCS measurements. This, in combination with confocal epi-illumination, highly sensitive avalanche photodiodes for fluorescence detection, and very selective bandpass filters to discriminate the fluorescence from the background, made it possible to improve signal-to-background ratios in FCS measurements by several orders of magnitude. In a dynamic system, the relative fluctuations increase as the concentration of molecules decreases. Therefore, in order to obtain high enough relative fluctuations in fluorescence, the number of molecules residing in the detection volume at the same time should not be too high. With the improvements mentioned above, the mean number of molecules could be kept low, without compromising the signal level, and measurement times could be shortened drastically, enabling a more widespread use of the FCS technique. A sensitivity that permits the detection of single molecules was reached. Although FCS, in a strict sense, cannot be categorized as a single molecule spectroscopy technique, the capacity of the technique strongly benefits from this high sensitivity.

2 Experimental Equipment – Aspects of the Standard Equipment

In order to realize the FCS experiment, a small illuminated volume must be created from which the fluorescence light

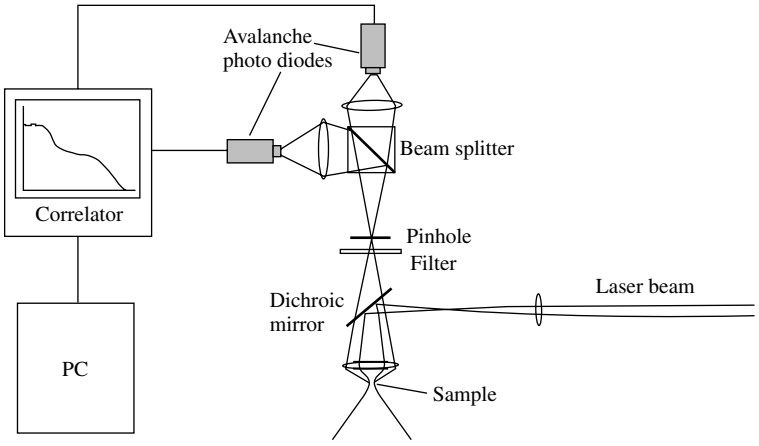

Fig. 1 Typical instrumentation for FCS experiments. A laser beam is directed via a dichroic mirror into a confocal microscope and focused by the objective into the sample. Emitted fluorescence from the sample is collected by the same objective, passes through the beam splitter, and is focused onto the image plane where the pinhole is located. The light passing the pinhole is spectrally filtered by highly selective bandpass emission filters and is focused onto the sensitive areas of the avalanche photodiodes. Standard TTL pulses from the diodes are fed to the PC-based correlator.

is collected and recorded. A typical FCS spectrometer is based on a confocal fluorescence microscope (Fig. 1). In contrast to confocal scanning, the confocal pinhole in FCS does not serve to enhance the spatial resolution. Its purpose is to reject the out-of-focus emission, and therefore it is larger than the point spread function of the objective. A typical range of diameters of the pinhole used in FCS is 30 to 100 μm. A laser is used as the light source for excitation. The main reason for using a laser is the possibility of focusing its well-collimated beam into a very small spot of about 0.5 μm in diameter. Additionally, the small spectral width of the laser light facilitates the spectral separation of the fluorescence emission from the excitation. The filter in front of the detector is usually a bandpass interference filter. At shorter wavelengths, it blocks the scattered laser light, and at longer wavelengths, it blocks the strongest band of Raman scattering from water. A typical sample is a dilute water-based solution of fluorescently labeled molecules. However, there is a relatively large flexibility in the choice of measurement environment. What is important is that the molecules are able to move in and out of the illuminated volume. This exchange of molecules is necessary for two purposes: (1) exchanging the photobleached molecules with the fresh ones or (2) measuring the kinetic parameters of the motion.

There are processes that can be studied by FCS on a spatially fixed set of molecules, or on just one fixed molecule, for example, intersystem crossing to the triplet state, photoisomerization, chemical reactions, or photon antibunching. However, at room temperatures, the fluorescent molecules photobleach after emitting typically 10^5 photons on the average. This is too few for a precise correlation analysis; therefore, the FCS experiments on fixed molecules have been performed almost only at cryogenic temperatures.

The experimental measurement of the fluorescence intensity $I(t)$ is accomplished by counting the number of photons, n, during time intervals of a predetermined width ΔT.

$$I(t) = I(i\Delta T) = \frac{n_i}{\Delta T}. \tag{2}$$

The time-dependent experimental correlation function is calculated as

$$G_{\text{exp}}(\tau) = G_{\text{exp}}(k\Delta T) = \frac{\frac{1}{M-k}\sum_{i=1}^{M-k} n_i n_{i+k}}{\left[\frac{1}{M-k}\sum_{i=1}^{M-k} n_i\right]^2}, \tag{3}$$

where M is the total number of counting intervals, so that the total duration of the measurement is $M\Delta T$.

3 Theory of FCS

3.1 Fluorescence Autocorrelation Function for Translational Diffusion

In FCS measurements, the macroscopic stochastic process of interest is the fluorescence intensity $I(t)$ detected from the observation volume. $I(t)$ depends on another stochastic process, namely, the concentration of fluorescent molecules, $C(\bar{r}, t)$, within the observation volume. Here, a brief derivation of the autocorrelation function for $I(t)$ will be given, restricted to the case in which translational diffusion of a single fluorescent solute into and out of the observation volume is the only process generating fluorescence fluctuations. This

case forms the basis for all kinds of dynamic systems that can be investigated with FCS.

In the majority of recent applications of FCS, a confocal microscope arrangement is used, where the observation volume is not physically restricted, such that molecules can freely diffuse into and out of it. It is defined by the dimensions of the laser beam focus, which excites the fluorescent molecules, and the collection-efficiency function of the microscope:

$$I(t) = Q\int_{-\infty}^{\infty} CEF(\bar{r})\, I_{\mathrm{exc}}(\bar{r})\, C(\bar{r}, t)\, \mathrm{d}V = Q\int_{-\infty}^{\infty} p(\bar{r})\, C(\bar{r}, t)\, \mathrm{d}V \qquad (4)$$

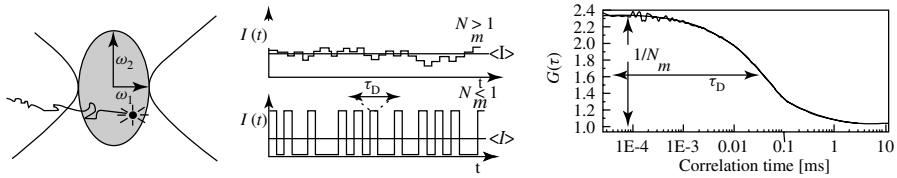
Here, $C(\bar{r}, t)$ is the concentration of fluorescent molecules at position $\bar{r}$ and time t. $Q = q\sigma_{\mathrm{exc}}\Phi_f$, where σ_{exc} is the excitation cross-section of the fluorescent molecules under study, Φ_f is their fluorescence quantum yield, and q signifies the efficiency of detection of fluorescence, which is emitted from the center of the laser focus. The latter includes the solid angle of light collection, the transmission of the microscope optics and the spectral filters, as well as the detection quantum yield of the detector. $CEF(\bar{r})$ is the collection-efficiency function, describing the dependence of light losses on the exact coordinates $\bar{r}$ of the light source in the sample. $CEF(\bar{r})$ is mainly defined by the cooperation of the objective and the confocal pinhole. $I_{\mathrm{exc}}(\bar{r})$ is the excitation intensity. The fluorescence emitted from a fluorophore molecule is normally assumed to be proportional to the excitation intensity. The product of $CEF(\bar{r})$ and $I_{\mathrm{exc}}(\bar{r})$, which defines the spatial dependence of brightness at which a molecule is seen by the detector, denoted by $p(\bar{r})$, is approximated to be Gaussian distributed in the axial as well as in the radial directions:

$$p(\bar{r}) = I_0 \mathrm{e}^{-2(x^2+y^2)/\omega_1^2} \mathrm{e}^{-2z^2/\omega_2^2} \qquad (5)$$

where I_0 is the peak excitation intensity in the center of the focused laser beam, and ω_1 and ω_2 denote the distance from this center in radial and axial dimensions respectively, at which the detected fluorescence has dropped by a factor, e^2 (see Fig. 2(a)). This simplification makes it possible to express the fluorescence autocorrelation function in a much simpler form and has been shown to be a reasonable approximation for most FCS instrumentations based on a confocal microscope arrangement. On the basis of this approximation, it is convenient to define a brightness profile, where $p(\bar{r})$ is normalized by the peak intensity I_0:

$$p_{\mathrm{norm}}(\bar{r}) = \frac{p(\bar{r})}{I_0} = \mathrm{e}^{-2(x^2+y^2)/\omega_1^2} \mathrm{e}^{-2z^2/\omega_2^2} \qquad (6)$$

The detected fluorescence intensity $I(t)$ is, for simplicity, assumed to be an ergodic and at least a wide-sense stationary stochastic process. Loosely speaking, this means that the time average of a process for, namely, one molecule over a longer time equals the ensemble average of the process for many molecules studied at a certain moment in time. Further, the correlation between two points in time for the process gets continuously smaller with increasing differences in time between the points. Since we can never get all possible realizations (outcomes) of $I(t)$ at our disposal, it would, without this assumption, be impossible to measure the true correlation function for $I(t)$ at some given conditions. However, with these assumptions, we can get a good estimation of the statistical properties of $I(t)$, such as the ensemble average and the autocorrelation function, if we measure



(a) (b) (c)

Fig. 2 (a) Schematic view of the observation volume (gray shaded area), given by the dimensions of the focused excitation laser beam (thick black line) and the collection-efficiency function, $CEF(\bar{r})$, of the confocal fluorescence microscope. Typically, the distribution of the detected fluorescence intensity can be approximated as a three-dimensional Gaussian distribution, as given by $p(\bar{r})$ in Eq. (5), where ω_1 and ω_2 are the distances from the center in the radial and axial directions at which $p(\bar{r})$ has dropped by a factor of e^2 compared to its peak value, $p(0)$. (b) The detected fluorescence intensity, $I(t)$, reflects the number of fluorescent molecules in the detection volume, which in FCS measurements, can be normally regarded as a Poisson process. For a Poisson process, the variance corresponds to the mean itself. For molecules freely diffusing into and out of the observation volume, the magnitude of the relative fluctuations (normalized with their mean, $\langle I \rangle$) increases with a lower mean number of molecules within the observation volume, N. (c) A typical FCS curve for a solute undergoing free diffusion in three dimensions into and out of an observation volume as that of Fig. 2(a). In FCS, the relative fluctuations of the detected fluorescence are quantified by the extrapolated autocovariance of $I(t)$ at $\tau = 0$, normalized by the mean intensity squared, $\langle I \rangle^2$. This corresponds to the amplitude of the time-dependent part of the normalized fluorescence autocorrelation function, given by Eq. (13), and equals $1/N$. The decay time, τ_D, of this function is related to the mean dwell time of the sample molecules in the observation volume, and can for translational diffusion be approximated as $\tau_D = 4D/\omega_1^2$, where D is the diffusion coefficient of the studied molecules.

one realization of $I(t)$ for a long enough time. Experimentally, the autocorrelation function of $I(t)$ is thus obtained from

$$R_{II}(\tau) = \frac{1}{T}\int_0^T I(t)I(t+\tau)\,\mathrm{d}t = \langle I(t)I(t+\tau)\rangle, \qquad (7)$$

where T is the measurement time. After normalization with the mean intensity squared and by assuming a wide-sense stationarity, the autocorrelation function of $I(t)$ takes the form

$$G(\tau) = \frac{R_{II}(\tau)}{\langle I\rangle^2} = \frac{\langle I(t)I(t+\tau)\rangle}{\langle I\rangle^2} = \frac{\langle \delta I(0)\delta I(\tau)\rangle}{\langle I\rangle^2} + 1 \qquad (8)$$

Here, $\langle I \rangle$ is the mean collected fluorescence intensity and $\delta I(t) = I(t) - \langle I \rangle$ denotes the fluctuation. The first term in the two last expressions corresponds to the autocovariance function of $I(t)$ divided by the mean intensity squared.

In order to compute this correlation function, the behavior of concentrations must be put into Eq. (8), using Eq. (4):

$$G(\tau) = \frac{Q^2 \iint_{VV'} p(\bar{r})p(\bar{r}')g(\bar{r},\bar{r}',\tau)\mathrm{d}V\,\mathrm{d}V'}{\left(Q\overline{C}\int_V p(\bar{r})\,\mathrm{d}V\right)^2} + 1 = \frac{\iint_{VV'} p_{\mathrm{norm}}(\bar{r})p_{\mathrm{norm}}(\bar{r}')g(\bar{r},\bar{r}',\tau)\,\mathrm{d}V\,\mathrm{d}V'}{\left(\overline{C}\int_V p_{\mathrm{norm}}(\bar{r})\,\mathrm{d}V\right)^2} + 1, \qquad (9)$$

where $g(\bar{r}, \bar{r}', \tau) = \langle \delta C(\bar{r}, t) \delta C(\bar{r}', t + \tau) \rangle$ is the concentration autocovariance function and $\overline{C}$ is the equilibrium mean concentration. The concentration fluctuations can be expressed as $\delta C(\bar{r}, t) = C(\bar{r}, t) - \overline{C}$. The propagation of $\delta C(\bar{r}, t)$ in space and time is described by the diffusion equation:

$$\frac{\mathrm{d}\delta C(\bar{r}, t)}{\mathrm{d}t} = D\nabla^2 \delta C(\bar{r}, t) \qquad (10)$$

with the boundary condition $\delta C(\bar{r}, t) = 0$ at $|\bar{r}| = \infty$. Here, $\nabla^2 = (\partial^2/\partial^2 x, \partial^2/\partial^2 y, \partial^2/\partial^2 z)$ and D is the diffusion coefficient of the fluorescent molecules. In solution, the diffusion coefficient is given by the Stokes–Einstein equation: $D = kT/6\pi\eta R$, where k is the Boltzmann's constant, T is the absolute temperature, η is the viscosity, and R is the hydrodynamic radius of the diffusing molecule.

Normally, FCS measurements are performed in dilute solutions that can be considered ideal. This means that the fluorescent molecules do not interact with each other. At any instant of time, a fluctuation in the concentration at a position $\bar{r}$ is independent of the fluctuation at any other position $\bar{r}'$. In addition, the number of molecules within any subvolume is governed by Poisson statistics. The Poisson distribution describes the number of times an event has occurred as a function of time, where the events occur at random times, independent of each other, and with a constant average intensity (i.e. number of events per time unit). For a Poisson process, the probability that exactly N events have taken place within a time interval $t = \{0, t_1\}$ is given by

$$P(t_1, N) = \frac{\mathrm{e}^{-\lambda t_1}}{N!}(\lambda t_1)^N \qquad (11),$$

where λ is the intensity. The average value and the variance equal each other, and are given by

$$\sigma^2 = \langle N \rangle = \lambda t_1 \qquad (12)$$

Given these assumptions, Eq. (9) can finally be written as

$$G(\tau) = \frac{1}{N}\left(1 + \frac{4D\tau}{\omega_1^2}\right)^{-1}\left(1 + \frac{4D\tau}{\omega_2^2}\right)^{-1/2} + 1 = \frac{1}{N}G_{\mathrm{D}}(\tau) + 1. \qquad (13)$$

N is usually called the number of molecules in the observation volume. For simplicity, and for later reference, the normalized functional form of the correlation function for translational diffusion has been denoted as $G_{\mathrm{D}}(\tau)$. Since the spatial brightness function $p(\bar{r})$ has no abrupt limits, the meaning of the "observation volume" and its size deserves some attention. Owing to the gradual fall in brightness, there is no evident border allowing one to say whether a molecule is in or out of the observation volume. The contribution of a molecule to the fluorescence intensity simply decreases with its distance from $r = (0, 0, 0)$. A natural way of selecting the volume would be to put its boundary through points with some constant value of $p(\bar{r})$. While there are no well-defined limits and no defined shape of the observation volume, its absolute size is exactly defined. It corresponds to the volume containing N molecules, where N is defined in Eq. (13). As a Poissonian process, the mean of the number of molecules in the observation volume corresponds to its variance (Eq. 12). The value of N can be calculated to be

$$N = \frac{1}{G(0) - 1} = \overline{C}\frac{\left(\int_V p_{\mathrm{norm}}(\bar{r})\,\mathrm{d}V\right)^2}{\int_V p_{\mathrm{norm}}^2(\bar{r})\,\mathrm{d}V} \qquad (14)$$

Consequently, as we can see from Eq. (14), the measured number of molecules is determined exclusively by the concentration, the dimensions, and the shape of the normalized brightness profile $p_{\mathrm{norm}}(\vec{r})$ of the observation volume, and does not depend on the excitation intensity I_{exc} and the quantum yield (specific brightness) of the molecules, Q. This is an important feature of FCS.

For a sample that contains m different species with different fluorescence quantum yields and with different diffusion properties, Eq. (13) can be generalized to

$$G(\tau) = \frac{\sum_{i=1}^{m}\left[N_i Q_i^2 \left(1+\frac{\omega_1^2\tau}{4D_{\mathrm{i}}}\right)^{-1} \times \left(1+\frac{\omega_2^2\tau}{4D_i}\right)^{-1/2}\right]}{\left[\sum_{i=1}^{m}(N_i Q_i)\right]^2} + 1 = \frac{\sum_{i=1}^{m} N_i Q_i^2 G_{\mathrm{D}i}(\tau)}{\left[\sum_{i=1}^{m}(N_i Q_i)\right]^2} + 1, \qquad (15)$$

where $Q_i = (q\Phi_{\mathrm{f}}\sigma_{\mathrm{exc}})_i$ is the fluorescence brightness of the ith species, q is the detection efficiency, Φ_{f} is the fluorescence quantum yield, and σ_{exc} denotes the extinction coefficient. $G_{\mathrm{D}i}(\tau)$ is defined in Eq. (13). Note that the different fluorescent species contribute to the amplitude of $G(\tau)$ in proportion to the square of their relative fluorescence brightness, and it can be strongly misleading to interpret the "apparent" number of molecules N_{m} as the true mean number of molecules in the observation volume

$$N_{\mathrm{m}} = \frac{\left[\sum_{i=1}^{m} N_i Q_i\right]^2}{\sum_{i=1}^{m} N_i Q_i^2} \qquad (16)$$

3.2 Reaction Dynamics and Translational Diffusion

In general, there are two criteria, of which at least one needs to be fulfilled in order to gain information about a reaction process from fluctuation analysis of the detected fluorescence intensity and FCS:

1. The chemical reaction must lead to a change in the diffusion properties of the fluorescent species under investigation.
2. The chemical reaction must lead to a change in the fluorescence quantum yield or the excitation cross-section of the reactants.

In this way, the typical duration of the fluorescence bursts because of the passage of fluorescent molecules through the excitation volume or the magnitude of the fluorescence emission per molecule, reflected by the fluorescence brightness parameter, Q (Eq. 4), is changed.

3.3 Reactions Leading to a Change in the Diffusion Properties

In case the first criterion above is fulfilled, and if in addition, the relaxation time of the chemical reaction is slower than the average dwell times of the molecules in the observation volume, the reactant and product molecules can be considered as

separate types of noninteracting species on the time scale of the dwell times. The autocorrelation function of the fluorescence fluctuations can then be expressed in the form given in Eq. (15). In the most simple case, with a fluorescently marked ligand with fluorescence brightness Q_{free} and diffusion coefficient D_{free}, which binds to a receptor leading to a ligand–receptor complex with Q_{bound} and D_{bound}, (Eq. 15) can be written as

$$G_{\text{D}}(\tau) = \frac{N_{\text{free}} Q_{\text{free}}^2 \left(1 + \frac{\omega_1^2 \tau}{4D_{\text{free}}}\right)^{-1} \left(1 + \frac{\omega_2^2 \tau}{4D_{\text{free}}}\right)^{-1/2} + N_{\text{bound}} Q_{\text{bound}}^2 \left(1 + \frac{\omega_1^2 \tau}{4D_{\text{bound}}}\right)^{-1} \left(1 + \frac{\omega_2^2 \tau}{4D_{\text{bound}}}\right)^{-1/2}}{[N_{\text{free}} Q_{\text{free}} + N_{\text{bound}} Q_{\text{bound}}]^2} \quad (17)$$

This form of the autocorrelation function is applicable to a broad range of ligand–receptor interactions, either in solution or on/inside cells, monitored via FCS (Fig. 3).

3.4 Reactions Leading to a Change in the Fluorescence Brightness

In the FCS measurements, transient nonfluorescent states, or states with a different fluorescence brightness, present themselves as fluorescence fluctuations superimposed on those caused by concentration changes due to translational motion of the fluorophores in and out of the sample volume element (see Fig. 4). In the presence of a chemical reaction and translational diffusion, the concentration fluctuations of molecules of the ith species at position $\bar{r}$ and time t are determined by the following set of differential equations:

$$\frac{\mathrm{d}\Delta C_j(\bar{r}, t)}{\mathrm{d}t} = D_j \nabla^2 \Delta C_j(\bar{r}, t) - \sum_{k=1}^{M} T_{jk} \Delta C_j(\bar{r}, t), \quad j = 1 \text{ to } M \quad (18)$$

where M is the number of species participating in the chemical reaction, T_{jk} represents the matrix of the kinetic rate coefficients, and D_j is the diffusion coefficient of the jth component. In its general form, the normalized autocorrelation function of the detected fluorescence fluctuations will show a complex dependence on the eigenvalues and eigenvectors of a matrix derived from (Eq. 18), including the reaction rates as well as the coefficients of the translational diffusion, and cannot be expressed in an analytical form. Fortunately, simplifications are often possible.

Generally, it has been shown that if either of the two following conditions is fulfilled

1. diffusion is much slower than the chemical relaxation time(s) ($\tau_{\text{D}i} \gg \tau_{\text{chem}}$) and/or
2. the diffusion coefficients of all fluorescent species are equal then fluorescence correlation function can be separated into two factors; the first, $G_{\text{D}}(\tau)$, which depends on transport properties (diffusion or flow) and the second, $X(\tau)$,

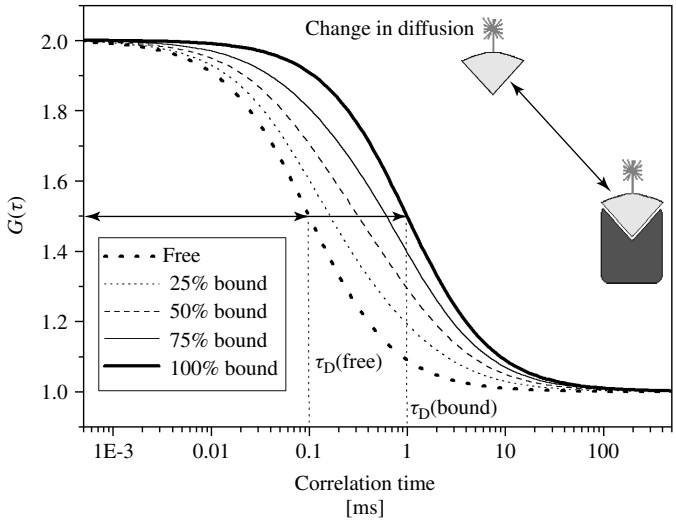


Fig. 3 Simulated FCS curves for a binding reaction involving a smaller, fluorescently marked molecule (ligand) binding to a larger molecule (receptor). In the simulation, the time range of the reaction is much longer than the passage times of the molecules through the observation volume. With a diffusion time of the ligand of 0.1 ms and that of the ligand–receptor complex of 1 ms, and with the fluorescence brightness of the molecules not being changed by the binding reaction, the fraction of bound ligands can be derived from the FCS curve as the fraction of molecules with a diffusion time of 1 ms (Eq. 17), with $Q_{\text{free}} = Q_{\text{bound}}$. The amplitude of $G(\tau)$ is not affected by the extent of binding.

which depends on the reaction rate constants:

$$G(\tau) = G_{\text{D}}(\tau)X(\tau) + 1 \qquad (19)$$

where

$$X(\tau) = \frac{\sum_{i,j=1}^{M} Q_i Q_j S_{ij}(\tau)}{\sum_{i=1}^{M} Q_i^2 \overline{C}_i} \qquad (20)$$

Here, Q_i denotes the fluorescence capacity of compound i and is defined in Eqs. 4 and 15. $S_{ij}(\tau)$ is the solution to the following set of differential equations and initial conditions:

$$\frac{\mathrm{d}S_{ij}(\tau)}{\mathrm{d}\tau} = \sum_{j=1}^{M} T_{ij} S_{jk}(\tau)$$
$$S_{ik}(0) = \overline{C}_i \Delta_{ik}, \qquad (21)$$

where T_{ij} corresponds to the reaction rate matrix of a reaction involving M different species, as given by Eq. (18). From Eqs. (20) and (21), one can see that $X(\tau)$ is a normalized sum of the terms $S_{ij}(\tau)$. Given an initial mean concentration, $\overline{C}_i$, of the compound i at $\tau = 0$, the terms $S_{ij}(\tau)$ state the average concentration of the state j at time τ, given that it was in state i at time 0.

It is, when possible, very convenient to be able to treat the kinetics of the

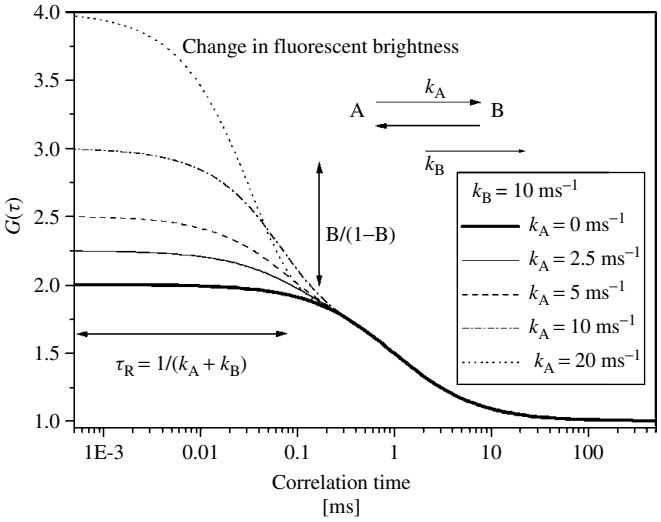

Fig. 4 Simulated FCS curves for a reaction, in which the fluorescence brightness of the participating molecules is changed. Here, a unimolecular reaction is considered, in which the compound B is nonfluorescent. The FCS curves can then be described by Eq. (19). The passage times of the molecules through the detection volume is for both A and B set to 1 ms, and the average total number of molecules in the observation volume $N = A + B$ is set to 1, such that A and B corresponds to the fractions of molecules in states A and B, respectively. The rate constant k_B has been given the value 10 ms^{-1}, and the values of k_A for the different curves are given in the inset. The relaxation time of the reaction, $\tau_{chem} = 1/(k_A + k_B)$, is much shorter than the passage times, such that the chemical reaction shows up as an additional relaxation process in the FCS curves. From Eqs. (19–21), it follows that the relaxation time of this process corresponds to τ_{chem}, and its amplitude is given by $B/(N(1 - B))$. The amplitude of the relaxation process due to diffusion corresponds to the total number of molecules participating in the reaction, $1/(A + B) = 1/N$, whereas the total amplitude represents $1/(AN)$, that is, the inverse number of fluorescently active molecules.

chemical reaction separately from the translational diffusion in the fluctuation analysis. As mentioned, a rather broad range of chemical reactions fulfills the above two criteria. In addition, for a reaction that does not fulfill the above criteria under standard conditions, it is sometimes possible to expand the observation volume, or to speed up the reactions under study, for instance, by using higher concentrations of unlabeled reactants, in order to make the relaxation time of the reaction faster than the dwell time (first criterion above).

3.5 Cross-correlation Modalities of FCS in the Spectral and Spatial Mode

By the use of two detector units, one will get two separate photocurrents. Following (Eq. 8), the normalized autocorrelation

function of the fluorescence intensities will then take the form

$$G(\tau) = \frac{\langle \delta I_1(0) \delta I_2(\tau) \rangle}{\langle I_1 \rangle \langle I_2 \rangle} + 1 \qquad (22)$$

where $\delta I_1(t)$ and $\delta I_2(t)$ signify the fluctuation terms in the detected fluorescence intensities in the first and the second detector, and $\langle I1 \rangle$ and $\langle I2 \rangle$ denote their corresponding mean values. One technical advantage of using two detectors in this way is that by cross-correlation, the shot noise inherent to photon detection can be eliminated. Of importance for measurements in the sub-microsecond time range is also the fact that the dead-time of the detectors can be circumvented. This makes it possible to follow fast processes by FCS down to the nanosecond time range. Another possibility is to let the two detectors cover different emission wavelength ranges, with the fluorescence intensity of the two emission ranges cross-correlated, the so-called dual-color FCS. In dual-color FCS, the observation volume is illuminated by two overlapping foci of two lasers with different wavelengths, in which one of the lasers selectively excites one of the two dye labels, and the other laser excites the other dye. However, under certain conditions, by the use of two-photon excitation or by the use of dyes with large differences in Stokes shifts, it is also possible to use only one laser as an excitation source for both dyes.

In a typical dual-color FCS experiment in which a bimolecular reaction is studied, two reaction partners are labeled with different dyes, for each of which the spectral range of the detectors is optimized. Upon binding, a new fluorescent species is formed, which is labeled with both of the dyes. In this way, the concentration and diffusion characteristics of two fluorescent species in solution as well as their reaction product can be followed in parallel (Fig. 5). For a bimolecular reaction, $A + B \leftrightarrow AB$, which is much slower than the translational diffusion of the molecules through the observation volume, three different experimental correlation functions are obtained. The normalized, time-dependent part of these functions can, in analogy to Eq. (16), ideally be described as

$$G_A(\tau) = \frac{1}{V} \times \frac{(K_A)^2 \overline{C}_A G_{D_A}(\tau) + (K_{Ab})^2 \overline{C}_{AB} G_{D_{AB}}(\tau)}{(K_A \overline{C}_A + K_{Ab} \overline{C}_{AB})^2} \qquad (23a)$$

$$G_B(\tau) = \frac{1}{V} \times \frac{(K_B)^2 \overline{C}_B G_{D_B}(\tau) + (K_{aB})^2 \overline{C}_{AB} G_{D_{AB}}(\tau)}{(K_B \overline{C}_B + K_{aB} \overline{C}_{AB})^2} \qquad (23b)$$

$$G_{AB}(\tau) = \frac{1}{V} \times \frac{(K_{Ab})(K_{aB}) \overline{C}_{AB} G_{D_{AB}}(\tau)}{(K_A \overline{C}_A + K_{Ab} \overline{C}_{AB})(K_B \overline{C}_B + K_{aB} \overline{C}_{AB})} \qquad (23c)$$

Here, V is the size of the detection volume, $\overline{C}_i$ denotes the mean concentration. $K_i = q_i \sigma_{abs(i)} \Phi_{f(i)} I_{exc(i)}$ is similar in meaning to Q_j and denotes the detected fluorescence per molecule, such that K_A is the fluorescence of species A registered at detector A, K_B is that of species B at detector B, K_{aB} is that of species AB at detector B (q_{aB}), and finally K_{Ab} is that of species AB at detector A. Likewise, q_i accounts for the detection quantum efficiency of the detectors and the transmittance of the fluorescence of species A to detector A (q_A), species B to detector B (q_B), species AB to detector B (q_{aB}), and species AB to detector A (q_{Ab}). $\sigma_{exc(i)}$ denotes the corresponding excitation cross-sections, I_{excA} and I_{excB} are the effective excitation intensities at

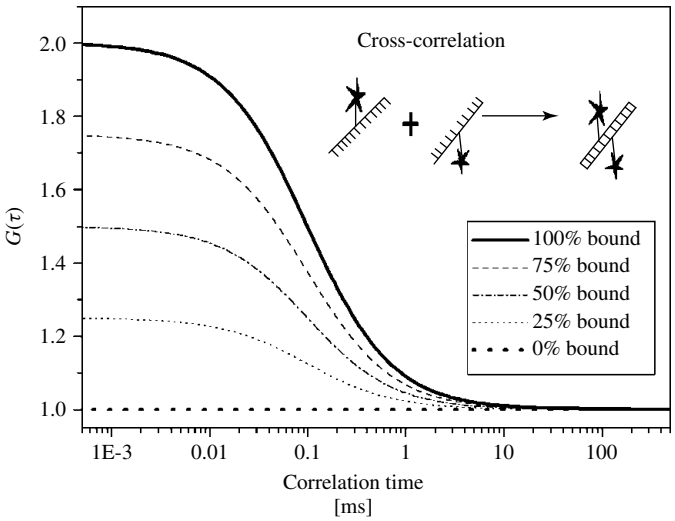

Fig. 5 Simulated experimental data of a dual-color cross-correlation experiment, where the association of two single-stranded, differently labeled, complementary DNA oligonucleotides is followed. The simulation is based on Eq. (23c), where the diffusion time of all species (the two single-stranded oligonucleotides, A and B, and the double-stranded product AB) is assumed to be 0.1 ms. The concentrations of the molecules are normalized so that $[\overline{C}_A + \overline{C}_{AB}]V = [\overline{C}_B + \overline{C}_{AB}]V = 1$, the fluorescence brightnesses are equal, $K_A = K_B = K_{Ab} = K_{aB}$, and the cross-talk in the fluorescence detection is neglected. As can be seen, the obtained information lies in the amplitude of the correlation curve.

the wavelengths where A and B are excited, and $\Phi_{f(i)}$ denotes the fluorescence quantum yields.

Depending on the choice of dyes and detection band pass filters, detection-unit cross talk, which generates additional terms to Eqs. (23a–c), has to be taken more or less into account. The cross-talk is related to the degree of overlap of the emission spectra of the dyes with that of the detection filters of the nondedicated channel.

The dual-color FCS approach can increase the selectivity and offers the possibility to follow the association/dissociation of a reaction product even if the reaction itself does not induce a change in either the diffusion properties or in the fluorescence capacity of the former reactants. The disadvantage is mainly the low signal-to-noise ratio that follows from the typically small amplitude of the cross-correlation term as well as from the fact that the fluorescence from all species will contribute to the denominator of Eq. (23c). Additionally, a less than perfect overlap of the volumes that the two detectors A and B observe can further reduce the amplitude of $G_{AB}(0)$. An imperfect overlap can be caused by the different extents of diffraction effects and aberrations in the optics at the two wavelengths.

The cross-correlation concept can also be applied in the spatial dimension. The fluorescence is then detected from more than one observation volume, which

makes it possible to measure velocities as well as directions of molecular transport processes.

3.6 Image Correlation Spectroscopy – Correlations in the Spatial Domain

In Scanning-FCS (S-FCS) experiments, a flow velocity is imposed by translating the sample at a uniform, known velocity through a laser beam. Theoretically, the FCS autocorrelation functions for uniform flow and for uniform sample translation are equivalent. For a uniform flow having a vectorial speed $\overline{V} = (v_x, 0, 0)$, directed perpendicular to the illumination of a Gaussian laser beam, where the diffusion is very slow, such that

$$\tau_1 = \frac{\omega_1^2}{4D} \gg \tau_f = \frac{\omega_1}{v} \tag{24}$$

the contribution due to translational diffusion can be neglected, and the normalized fluorescence autocorrelation function for one fluorescent species simplifies to

$$G(\tau) = \frac{1}{N} G_D(0) \times e^{-\left[\left(\frac{v_x \tau}{\omega_1}\right)^2\right]} + 1 \tag{25}$$

Image Correlation Spectroscopy (ICS) is an extension of S-FCS, which is based on quantitative analysis of confocal laser scanning microscopy images. As the scanning velocity is known, a fluorescence autocorrelation function in the spatial domain, which is equivalent to that in the time domain of Eq. (25), can be formed

$$G(\xi) = \frac{\langle \delta I(x) \delta I(x+\xi) \rangle}{\langle I \rangle^2} + 1 \tag{26}$$

where only the scanning velocity, v_x, as a scaling factor differs ξ from τ

$$\xi = v_x \tau \tag{27}$$

For a two-dimensional array of pixels, it is possible to extend (Eq. 26) to a two-dimensional spatial autocorrelation function with two independent variables, x and y:

$$G(\xi, \eta) = \frac{\langle \delta I(x, y) \delta I(x+\xi, y+\eta) \rangle}{\langle I \rangle^2} + 1, \tag{28}$$

which for an $N \times M$ pixelated image can be calculated and normalized as

$$G(\xi, \eta) = \frac{(1/NM) \sum_{k=1}^{N} \sum_{\ell=1}^{M} I(k, \ell) I(k+\xi, \ell+\eta)}{\left((1/NM) \sum_{k=1}^{N} \sum_{\ell=1}^{M} I(k, \ell) \right)^2} \tag{29}$$

where $M \gg \xi$ and $N \gg \eta$. From a computational point of view, it is more convenient to calculate the two-dimensional spatial autocorrelation function from the inverse Fourier transform of the power spectrum of the image data. The power spectrum is calculated as the product of the Fourier transform of $I(x, y)$ and its complex conjugate

$$G(\xi, \eta) = F^{-1}\{F[I(x, y)] \times F^*[I(x, y)]\} \tag{30}$$

In analogy to the expression for the autocorrelation function for S-FCS (Eq. 25), the autocorrelation function for ICS will take the form

$$G(\xi, \eta) = G(0) \times e^{-(\xi^2 + \eta^2)/\omega_1^2} \tag{31}$$

In both S-FCS and ICS measurements, the temporal/spatial dependence of the fluorescence autocorrelation function gives information only about the radius of the excitation laser beam and the scanning velocity, and does not normally contain

information about the sample molecules themselves, unless the molecules or aggregates are larger than ω_1. Instead, the relevant information is to be found in the amplitude $G(0)$, from which the density of molecules or the density of aggregates and the average number of monomers per aggregate can be determined.

In S-FCS and ICS, the amplitudes of $G(0)$ of Eqs. (25 and 31) can be expressed in a similar way as in Eq. (15). However, for cases in which there is a distribution of aggregates, an additional contribution to the amplitude can be expected from the variation of the aggregate size. Assuming that the fluorescence brightness, Q, of each monomer contained in an aggregate is unaffected by the number of monomers, $\mu_1(1)$, in the aggregates, one can show that

$$G(0) = \frac{1}{N_{\text{mono}}^2} \sum_i N_i(\mu_1(i)^2 + \sigma_i^2) \quad (32)$$

where N_{mono} is the mean number of monomers within the observation volume, $\mu_1(i)$ and σ_i are the mean and the variance of the number of monomers within the ith population of clusters investigated, and N_i is the mean number of such aggregates.

Since confocal microscopic images can be generated within less than a second, ICS measurements are faster than those of S-FCS. The image is also more easily collected over a large cell area so that more sampling, which leads to a higher accuracy, is done. On the other hand, the sampling is performed with a lower resolution, leading to a lower precision than that for S-FCS. ICS has been applied to yield a quantitative measure of the degree of aggregation of fluorescently labeled molecules, primarily cell membrane proteins and lipids.

3.7 Rotational Diffusion

The processes of absorption and emission of light by fluorescent molecules are anisotropic. Therefore, in general, fluctuations in detected fluorescence also occur because of rotational movement of molecules.

These fluctuations can occur even if the excitation beam is unpolarized, or if fluorescence is detected from only one direction. If the absorption dipole moment of the molecule is turned parallel to the direction of propagation of the excitation beam, then there will be no absorption. Similarly, if the emission dipole moment points to the detector, the light will be emitted in all other directions, except for the axis connecting the molecule and the detector. The magnitude of these orientational fluctuations can be enhanced by the use of polarized excitation and detection.

Despite the general presence of orientational fluctuations in fluorescence, the experimental evidence is scarce. There are several reasons for this. First, if the rotation is very fast, like that of organic dye molecules in water, then the fluctuations are masked by a quantum effect called *photon antibunching*. Second, if the slowly rotating macromolecule carries many fluorescent labels, the dipole moments of different fluorophores can be oriented at different angles, resulting in a significantly reduced dependence of absorption and emission on the orientation of the macromolecule. Finally, when labeled to a macromolecule, a dye can typically undergo wobbling motion due to a nonrigid attachment of the dye to the molecule of interest, such that the rotational motion rather reflects the wobbling of the dye than the rotational motion of the molecule to which it is labeled.

On the other hand, FCS provides an interesting feature in the fact that the rotation measurement is decoupled from the excited state lifetime τ_e, since the orientation is probed by two consecutive excitation cycles of the molecule. This allows, in principle, the measurement of very slow rotational diffusion, which is inaccessible to macroscopic fluorescence methods.

3.8 Higher Order FCS and Fluorescence Intensity Distribution Analysis (FIDA)

Although it is an extremely sensitive and fast method, FCS does not utilize all the information that is present in the fluorescence fluctuations; for example, if we analyze a mixture of two or more fluorescent compounds, then the components are separated on the basis of different diffusion times. The contributions of the components to the amplitude of the correlation function are proportional not only to concentrations but also to the square of the brightness (i.e. quantum yield in the elementary theory) of the corresponding components (Eq. 16). Therefore, the determination of actual concentrations of components in the mixture requires additional information. It is also possible that some of the components have equal diffusion coefficients, and differ only by the brightness of fluorescence.

Alternative approaches to gain complementary information about formation and number distributions of aggregates in a solution or on a surface exist. Here, we will briefly describe two approaches: (1) the use of higher order autocorrelation functions and (2) how generation of photon counting histograms, or fluorescence intensity distribution analysis (FIDA) can be used to gain complementary information for FCS analysis.

Higher order autocorrelation functions for the fluctuations in the detected fluorescence can be defined as

$$G_{m,n}(\tau) = \frac{\langle(\delta I(t+\tau))^m(\delta I(t))^n\rangle - \langle(\delta I(t))^m\rangle\langle(\delta I(t))^n\rangle}{\langle I(t)\rangle^{m+n}} \tag{33}$$

where m and n are integers. For n, $m = 1$ (Eq. 33) reduces to the standard second-order autocorrelation function (Eq. 8). (The average fluctuations, $\langle\delta I(t)\rangle$, contained in the second term of the numerator equals zero.) For a second-order autocorrelation function, the amplitude is given by Eq. (14). However, for the case in which the sample contains several species, or one or several distributions of aggregates, more than one measured parameter, as that of $G(0)$, is needed to characterize the concentrations of the different species/aggregates in the sample (Eqs. 15 and 32). One way of obtaining more information from a temporal or spatial record of fluorescence fluctuations is to make use of higher order autocorrelation functions, as defined in Eq. (33).

Fluorescence Intensity Distribution Analysis (FIDA), or Photon Counting Histograming (PCH) extracts information about the actual concentrations and brightnesses of the molecules present in the fluorescence fluctuations. In FIDA, the intensity signal needs to be prepared and analyzed in a different way compared to FCS, but the experimental arrangement is nearly identical. In the processing of the recorded photon counts, a histogram of the photon count numbers is calculated, instead of computing the correlation function $G(\tau)$, as done in FCS. The fluorescence photons are counted in time intervals of, for example, $\Delta T = 40\,\mu s$ during the experiment with duration

$M \cdot \Delta T$. Dividing by the total number of intervals M transforms the histogram into a photocount number probability distribution $P(n)$.

The parameters extracted by FIDA are concentrations c_i and molecular brightnesses Q_i of the species i. No information about diffusion is obtained by FIDA. If the components should have equal brightness values Q, then FIDA could not resolve them. In this respect, FIDA and FCS are complementary methods, which extract different but unique data from the same signal.

It is important to note that although the FIDA theory ignores the diffusion, it is still vital for the method, acting as the source of molecule number fluctuations.

From the aspect of utilizing the fluctuation signal, it seems natural to combine the two complementary methods – FCS and FIDA. One example of such a combination has been realized in FIMDA (Fluorescence Intensity Multiple Distributions Analysis), which is an extension of FIDA. Here, several distributions are collected simultaneously, effectively using several counters in parallel, with different counting time intervals ΔT_i. In the resulting set of distributions, the same photocounts are used, but they are grouped using different time windows.

4
FCS Applications in Life Sciences, Biomedicine, and Drug Discovery

In this section, several examples will be given in order to illustrate some of the approaches of the FCS technique (Sect. 3). It is beyond the scope of this review to list all possible applications; rather, we give some examples in order to illustrate the potential of this technique. Fluorescence Correlation Spectroscopy is a powerful tool for examining molecular interactions of biological importance with very high specificity. The ability to study specific interactions by FCS and related techniques show considerable promise as these techniques could be used as tools in genomics and proteomics, and with respect to drug discovery/screening. In this chapter, we will exemplify how different categories of specific interactions can be monitored by FCS techniques in Sects. 4.1 to 4.5.

4.1
Protein–Protein Interactions

Proteins play a crucial role in virtually all biological processes. The first step in the action of a protein is its binding of another molecule. Proteins as a class of micromolecules are unique in being able to recognize and interact with highly diverse molecules. Proteins can also interact with themselves or with other proteins thereby performing a wide diversity of important functions. The spectrum of functions a protein can perform ranges from mechanic to protective functions. The blood protein fibrinogen can form insoluble fibers resulting in blood clotting. Important protective proteins such as antibodies or immune globulins bind with and thus neutralize foreign proteins and render them inactive, enabling the immune system to distinguish between self and nonself. Further, the hormone proteins bind to receptor proteins and thus carry messages throughout the body. Finally, molecular self-assembly can serve as a good example of protein–protein interaction that can play a fundamental role in biology. The assembly of identical molecules such as peptide and protein into aggregates in bulk at surfaces or

interacting with macromolecules is, to an increasing extent, believed to be a cause of diseases such as Alzheimer's disease, prion diseases, and others.

As an example, and to give a general idea of how FCS can be used to study protein–protein interactions, and in particular, aggregation processes of peptides and proteins, the aggregation of the Alzheimer amyloid β-peptide (Aβ) will be discussed. The aggregation process has been studied *in vitro* with different techniques: turbidimetry, light scattering, analytical ultra-centrifugation, circular dichroism spectroscopy, electron microscopy, atomic force microscopy, polyacrylamide gel electrophoresis, size exclusion chromatography, and quantitative fluorimetry. However, only the spectroscopic techniques allow the measurement of the aggregation process directly in solution. So far, quasi-elastic light scattering has provided the most detailed description of this process. Recently, the aggregation of Aβ and the protein–protein interaction in plant cells have been studied using FCS. In order to follow the polymerization process, it is necessary to label the peptide/protein with at least one fluorophore with an account on steric effects of the fluorophore molecules. Further, it is extremely important to pay attention to the buffer composition and its pH value used for the aggregation experiment. Data on the Aβ-aggregation process have been evaluated using the correlation function as given in Eqs. (15–17) (see Sect. 3.3). The aggregation of Aβ dissolved in Tris-buffered saline, pH 7.4, occurs above a critical concentration of 50 μM and proceeds from monomers/dimers into two discrete populations of large aggregates, without any detectable amounts of oligomers (Fig. 6). The polymerization of Aβ is a highly cooperative process in which the formation of very large aggregates precedes the formation of fibrils. The aggregation was reduced when Aβ was incubated in the presence of Aβ ligands, oligopeptides previously shown to inhibit fibril formation. The aggregation process occurs in two phases. In the early phase (1–120 min), diffuse networks and fibrils are formed. Previous studies, performed with other techniques, have provided limited information on the early (1–120 min) phase in the Aβ aggregation due to problems in measuring monomers, oligomers, and large aggregates simultaneously. The FCS technique is not limited by these problems, and measurements are made directly in solution without any further sample preparation thereby minimizing the risk for artifacts. In conclusion, FCS can be used as a highly sensitive and specific competition assay to identify potential inhibitors for the Aβ–aggregation process, and the appearance of aggregates in the cerebrospinal fluid of Alzheimer's patients using FCS is suggested as a diagnostic tool. FCS offers a powerful tool to study the aggregation process. It allows the polymerization process to be followed from the start point in real time, detecting monomers, oligomers, and large aggregates in solution simultaneously. In addition, FCS provides a fast and specific analysis of the aggregation process with high sensitivity. Further, it is reasonable to assume that analysis of the fluorescence raw data with FIDA/PCH (see Sect. 3.8), can extend the precision and accuracy further. FIDA/PCH offers complementary information to FCS, and makes it possible to distinguish aggregates from their different fluorescence brightness, which at least ideally scales linearly with the size of the aggregates. FCS, on the other hand, differentiates species based on their diffusive speed, which scales with the cubic root of the molecular size.

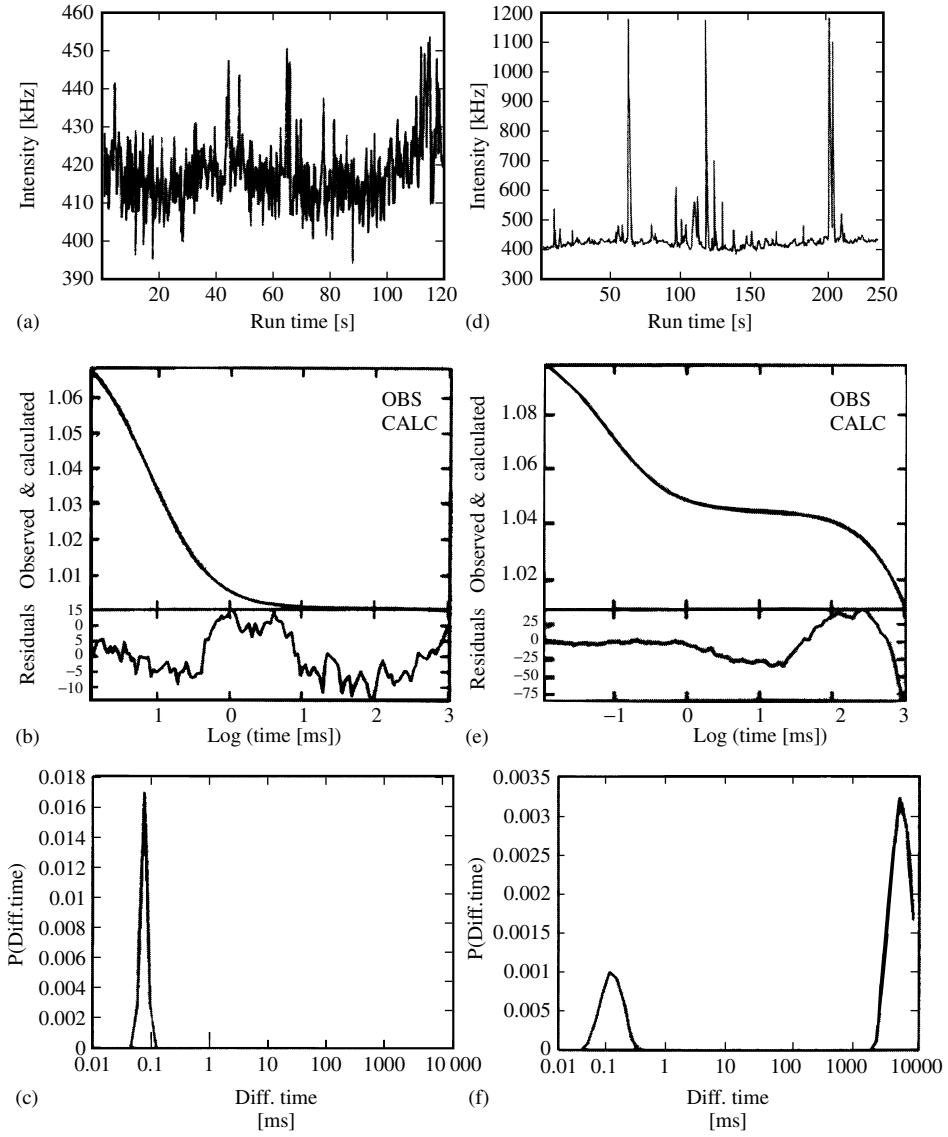

Fig. 6 The polymerization of Aβ studied by FCS using rhodamine-labeled Aβ as fluorescent probe (Eqs. 15 to 17, Sect. 3.3). Aβ (80 µM) was incubated with rhodamine-labeled Aβ (10 nM). The fluorescence intensity fluctuations were measured after (a) 2 min and (d) 40 min. The corresponding autocorrelation functions were calculated according to Eq. (34). (b) The monophasic form of the curve indicates that the diffusion times for the species present are similar. The diffusion time, τ_D, was found to be 90 µs. (e) After 40 min of incubation, the calculated autocorrelation function has a biphasic appearance. Species with a very high diffusion time ($\tau_D = 3$ s), corresponding to very large aggregates, as well as the initial monomers/dimers ($\tau_D = 90$ µs) can be observed. The distribution of diffusion times was calculated from the autocorrelation function using the CONTIN program (c and f).

According to estimations, a relative difference in diffusive times between two different molecular species of at least a factor of 1.6 is necessary, if the species have comparable quantum yields and high fluorescence signals.

4.2 Ligand–Receptor (on Single Live Cell) and Intracellular Interactions

The receptor concept is the primary theoretical basis for modern pharmacology. Drugs, hormones, neurotransmitters, toxin, and other biologically active substances can be referred to as ligands. Ligands exert their actions by way of interaction with receptors. The resulting receptor–ligand complexes produce alterations in physiological processes. For certain ligands (e.g. peptides, natural products), it is not possible to detect receptors with the conventional method radiography. If the numbers of receptors are few per cell, specific binding is difficult to detect because of the background. The radiography method includes several washing steps to remove unbound ligand. The half-life of the receptor–ligand complex is often shorter or similar to the time required for separations of free and bound ligands. Therefore, interactions between certain ligands and their different receptors are often overlooked by the conventional binding technique. The single-molecule detection sensitivity of FCS and its short measurement time can often provide a way to overcome these difficulties allowing receptor–ligand interactions to be followed in living cells, even if the receptors are present only in very sparse numbers.

The ligand–receptor interactions can be analyzed on the basis of the approach and the fluorescence intensity autocorrelation function as given in Eq. (17). In FCS measurements, the fluorescence intensity fluctuations are recorded from only those molecules that diffuse through the confocal laser volume element. The time required for the passage of fluorescent molecules through the volume element is determined by the diffusion coefficient, which is related to the size and shape of a molecule. Thus, diffusion times obtained from the analysis of fluorescence intensity fluctuations with autocorrelation functions allow differentiating faster diffusing and slower diffusing molecules, that is, in this context, to distinguish free ligands from ligand–receptor complexes (Sect. 3.3). In binding studies with the FCS technique, a mixture of several ligand–receptor complexes (components) with different molecular weights and corresponding different diffusion times can be analyzed without any need to physically separate unbound components from bound ones. Since in the FCS technique diffusion times of ligand molecules and ligand–receptor complexes are used as characteristic parameters for binding analysis, distribution of diffusion times can be obtained via a special algorithm that can reveal the appearance of several binding complexes. For the evaluations of the distribution functions, the CONTIN program using restrained regularization was applied. Instead of an evaluation of discrete diffusion processes with distinct species and characteristic diffusion times, the dynamic motion of receptor complexes in membranes is considered to be distributed with regard to their diffusion times. This program can thus be used to validate the presence of discrete ligand–receptor complexes in which the appearance of two binding complexes found by distribution analysis of diffusion times may suggest that these are representations of two different forms or subtypes of ligand–receptor

complexes. Ligand–receptor interactions in live cells using FCS have been performed in several laboratories. In what follows, an example will be given to illustrate how FCS can be used to investigate the interaction of ligands with their cognate receptors. In order to highlight ligand–receptor interactions on live cells (cell cultures) using FCS, the interaction between the ligand proinsulin C-peptide (CP) and its receptor will be demonstrated. It is very important to take background fluorescence into account for the judgment of specific ligand–receptor interaction when a ligand is tagged with a fluorescent dye. Background fluorescence usually originates from endogenous proteins if their excitation wavelength is close to that of the dye used. The endogenous proteins such as NADH and FAD produce autofluorescence in blue–green range. Therefore, sometimes it is advantageous to make excitation in near-IR range, where autofluorescence is less prominent. Fluorescence signals will be overestimated if they are not corrected for background fluorescence. In order to check background fluorescence, the autofluorescence was measured in cells without the addition of fluorophore labeled ligands. Background fluorescence differs very much depending on cell types. For example, at 514-nm excitation, very little background fluorescence was detected in human diploid fibroblasts, pancreatic insulinoma cells, and renal tubular cells, whereas huge background fluorescence was observed in endothelial cells from umbilical cord veins. CP was covalently labeled with the fluorophore rhodamine (Rh) and binding of Rh–CP was conducted in human renal tubular cells.

Fluorescence intensity fluctuations and autocorrelation functions of Rh–CP free in solution and bound to human renal tubular cell membranes are presented in Fig. 7. Examination of the Brownian motion of unbound Rh–CP in the buffer medium above the cell surface exhibits typical fluctuations (Fig. 7a) and a diffusion time (τ_{D1}) of 0.15 ms (Fig. 7b). When the volume element is positioned at the level of the cell membrane, the fluorescence intensity traces exhibited several prominent peaks (Fig. 7d). These peaks, with up to three times higher intensity than the baseline, are a clear representation of the Brownian motion of ligand–receptor complexes containing several rhodamine-labeled CP molecules. Correlation analysis of the intensity fluctuations then reveals a diffusion process of the cell-bound C-peptide with at least two components characterized by diffusion times of $\tau_{D2} = 1$ ms and $\tau_{D3} = 80$ ms, respectively (Fig. 7e). The results indicate the presence of specific binding of human proinsulin C-peptide to its membrane-bound receptors since bound Rh-CP is displaced following addition of 1000-fold molar excess of unlabeled C-peptide (Fig. 7f). Further evidence for the binding specificity of C-peptide is obtained from the fact that addition of excess unlabeled C-terminal pentapeptide was accompanied by displacement of bound Rh-CP, similar to what was observed after the addition of intact C-peptide. This suggests that the C-terminal segment is involved in the binding process (Fig. 7c).

Among other applications of FCS within this category, it has also been applied to precisely study ligand–receptor interactions for the purified acetylcholine receptors in solution. Using FCS, the C-peptide specific binding to macromolecules obtained from detergent-solubilized cell materials has also been shown. Further, combining imaging by confocal laser scanning microscopy and FCS (LSM-FCS) has made it possible to make images of ligand–receptor interaction and its dynamics

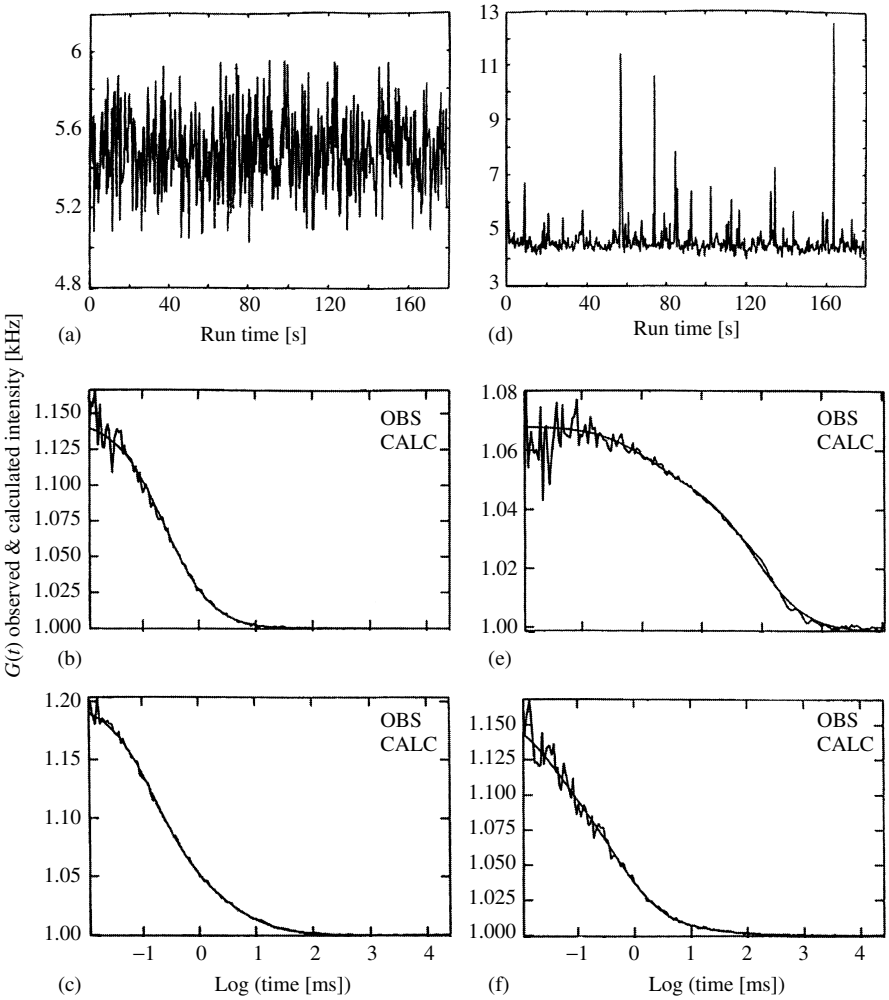

Fig. 7 C-peptide binding and displacement to the membranes of cultured renal tubular cells (Eq. (17), Sect. 3.3). (a) Fluorescence intensity fluctuations, (b) autocorrelation function for Rh-CP (5 nM) free in solution, $\tau_D = 0.15$ ms. (d) Fluorescence intensity fluctuations and (e) autocorrelation function for Rh-CP bound to membranes on the cell surfaces. Diffusion times (τ_D) and corresponding fractions (γ): $\tau_{D1} = 0.15$ ms, $\gamma_1 = 0.1$; $\tau_{D2} = 1$ ms, $\gamma_2 = 0.15$; $\tau_{D3} = 80$ ms, $\gamma_3 = 0.75$. Autocorrelation functions of displacement of membrane-bound Rh-CP by postincubation of a 1000-fold molar excess of (f) nonlabeled C-peptide and (c) nonlabeled C-terminal pentapeptide. In postincubations, renal tubular cells were first incubated with binding buffer containing 5 nM Rh-CP for 60 min and observed binding was treated as control. Then 5 µM nonlabeled CP or nonlabeled C-terminal pentapeptide was added to the same cells, incubated for three more hours, and checked for displacement.

in live cells. The LSM-FCS setup enables the determination of localization, topology, and transport of proteins in living cells, and the visualization and dynamic characterization of lipid bilayers. The LSM-FCS setup appears to be a very valuable technique to study ligand–receptor interactions in any part of living cells and/or cell compartments.

Having outlined the capacity of the FCS technique for cell surface studies, it is also important to emphasize that the measured parameters always have to be carefully evaluated with respect to artifacts. If not considered, photobleaching in the laser excitation beam and the limited reservoir of fluorescent molecules on the cell surface can lead to an underestimation of the density of receptor molecules on a cell surface. The adjustment of proper laser intensity requires great attention, both with respect to the dye and the cell survival. The extent of depletion of a fluorescent compound on a cell surface as measured with FCS depends on several parameters (e.g. diffusion speed, area of free diffusion, excitation intensity, and time of laser exposure). The depletion can thus not only lead to a reduced overall surface density but can also significantly skew a distribution of several diffusion species.

In addition to photobleaching, the incorporation of fluorophore into the ligand is an important factor in receptor binding studies with fluorescently labeled ligands. Ideally, the dye-labeled ligands should not contain unbound dye molecules as they may contribute to nonspecific interactions. Since dye–ligand complexes usually have a certain half-lifetime, the purity of dye-labeled ligand complexes should be checked from time to time (even 100% dye-labeled ligands lose their dye molecules (5–10%) after 2–3 months). A problem concerning ligand tagging is the labeling of low molecular weight ligands, which is related to the limitation of FCS to distinguish molecular sizes by translational diffusion. The increase in molecular weight of a labeled ligand by a factor of 8 only doubles its diffusion time (following from the Stokes–Einstein equation, see text following Eq. 10). It is thus sometimes difficult to distinguish the diffusion time of a dye-labeled ligand from that of the dye, particularly if the molecular weight of the ligand is less than that of the dye molecule (Sect. 4.1). However, Häberlein's group has been successful in labeling low molecular weight ligands with rhodamine when the ratio of molecular weights of the rhodamine-labeled kavain ligand and rhodamine was two. Further, in binding assays with dye-labeled ligands, there is always a risk that a dye can interfere with the affinity due to steric effects. This depends both on the structure of the dye and the position of the ligand to which the dye molecule is tagged. Therefore, it is important to check the activity of the dye-labeled ligands in functional studies. If the dye-labeled ligand fails to produce functional activity, it is advisable either to use another dye or to tag the dye to another position.

FCS analysis of ligand–receptor interactions in cell cultures demands a healthy state of cells. Nonliving cells are unsuitable for receptor binding studies with FCS. To this point, the lifetime of cells is a limiting factor for FCS measurements, where certain cells (e.g. fibroblasts) survive longer than others (e.g. neuronal cells). Membranes of dead cells lack the fluidity of the phospholipid environment, which leads to immobility of ligand–receptor complexes. Washing of the cells, a way to reduce background fluorescence – in this case, usually done 4 to 5 times with PBS – has to be done with care since this washing can also induce damages to cells. Low ionic strength

and temperature of the binding buffer can destroy cells. The pH of the binding buffer must be close to 7.4.

If the ligand–receptor interactions are followed on membranes of cultured cells, it is very critical that the focus of the laser beam is properly positioned on the membrane surface. It is a difficult task to be sure that the focus is exactly on the membrane. As a hint, we propose that if receptor binding is observed, a change of the focus 1 μm upward should lead to a reduction of the binding. One should take into consideration that if the receptor is membrane-bound, the binding observed in the cytoplasm is mostly nonspecific. In certain cases, if the focus is in the cytoplasm, one detects the internalization of receptors. If cells are cultured in eight-well Nunc chambers, it is useful to have them attached to the bottom of the chamber (Nunc chamber is usually used for the cell culture. In FCS technique, it is used as a sample chamber. It has a cover glass in the bottom, suitable for an inverted microscope). During the FCS measurement, cells should not move since a change of cell position during the measurement is likely to introduce errors.

Performing FCS measurements intracellularly confronts the practitioner with more challenges, in terms of photobleaching, autofluorescence, cell viability, and so on. For intracellular measurements, two-photon excitation has proved to be a useful mode of excitation. Two-photon excitation as a single quantum event was first predicted by Göppert-Mayer in 1931. It arises from the simultaneous absorption of two photons that combine their energies to cause the transition to the excited state of the fluorophore. The first experimental verification of this phenomenon could not be accomplished until the invention of lasers 30 years later. In 1990, two-photon excitation of fluorescence was introduced in laser-scanning microscopy as a new tool within biophysical research and given the name two-photon laser-scanning microscopy (TPLSM). Most of the properties that make TPLSM attractive derive from the quadratic dependence of the excitation probability on the excitation light intensity. In a strongly focused excitation beam, this quadratic dependence makes the excitation outside the focal region fall off with the fourth power of the distance from the focal plane in the axial direction. Since photobleaching can be considered to roughly scale with the excitation rate, out-of-focus photobleaching and attenuation of the excitation beam by out-of-focus absorption does not occur to any significant degree. Owing to the inherent confinement of the excitation volume in TPLSM, spatial filtering (pinhole) in the image plane is not necessary. This confinement also allows a greater flexibility in the detection procedure in the sense that the emitted light does not have to pass through the microscope objective, and the emitted light does not have to be focused, so that scattering of the fluorescence may occur without any loss of detection efficiency. Moreover, detection of two-photon excited fluorescence is not hampered by a high background owing to Raman and Rayleigh scattering of the excitation light. These features are attractive for FCS experiments, in particular, intracellular studies. FCS experiments with two-photon excitation in which the diffusion of fluorescently labeled beads were followed in the cytoplasm of live mouse fibroblast cells were first demonstrated in 1995. In further studies, intracellular dynamic processes have been followed by two-photon FCS, utilizing, for example, green fluorescent proteins (GFPs). Two-photon excitation can also be combined with one-photon excitation

such that two-color cross-correlation FCS can be performed with only one excitation wavelength.

4.3 Vesicle–Peptide Interactions

Phospholipid vesicles and artificial membrane systems have been studied intensively as a way of determining the properties of biological membranes. With vesicles it is easier to manipulate the various parameters of the membrane system and thus, to investigate membrane-bound enzymes and membrane transport systems without possible interfering reactions that occur in the cell membrane. One important use of vesicles is as vehicles in drug therapy. Vesicles, prepared with drugs entrapped inside, are being used as carriers for these drugs to target organs, thereby avoiding digestion and unwanted metabolic effects during delivery after intake. The interior of the vesicle is an aqueous environment, and with the extrusion technique, it is possible to prepare vesicles with different substances/dye molecules entrapped inside. Thus, the external and internal environment of phospholipid vesicles can be manipulated, and studies can be conducted on a variety of properties of these synthetic membranes, including their ability to incorporate or release molecules, and their interaction with various substances (peptides, proteins, nucleic acids).

In earlier studies, interactions between proteins and vesicles have been performed using different biochemical procedures, but very little has been done using FCS. However, recently some studies have been performed indicating the promise of FCS for these kinds of studies. The following example demonstrates how FCS has been applied to study molecular interactions between peptides/proteins and vesicle membranes based on the concept as given in Eqs. (15) to (17) (Sect. 3.3). Molecular interactions of melittin, a pore-forming peptide, and magainin, a membrane-breaking peptide, with phospholipid membranes were performed in rhodamine-entrapped vesicles (REV) and in rhodamine-labeled phospholipid vesicles (RLV). The REV entrapped free rhodamine inside could be released out of REV if pores/channels were formed into vesicles, or if they were broken. In contrast to REV, RLV did not entrap free rhodamine inside since rhodamine was covalently bound to the head groups of phospholipids. Therefore, the formation of channels into RLV could not result in rhodamine release in solution and only breakage of RLV could make free rhodamine appear freely in solution. Free rhodamine was used to calibrate the instrument as a reference to estimate diffusion times of the vesicles, and to justify whether the vesicles were intact or broken. The diffusion times of free rhodamine and vesicles were determined separately. The concentration ratio of peptide: phospholipid ranged from 1 : 1 to 1 : 40. At least a ratio of 1 : 20 (peptide : phospholipid) was necessary to obtain pronounced effects of peptides on vesicles.

Intensity autocorrelation functions $G(\tau)$ of free rhodamine and vesicles are shown in Fig. 8. Diffusion times (τ_D) of free rhodamine in solution (Fig. 8a), of REV vesicles with rhodamine entrapped inside as well as of RLV vesicles with rhodamine covalently bound to the head groups of phospholipids and not entrapped inside (Fig. 8b, c) are found to be 0.063 and 9 ± 1 ms respectively. Similar diffusion times are obtained when autocorrelation functions (Fig. 8a–c) are analyzed with the CONTIN program (see Sect. 4.2) with regard to the distribution of diffusion times

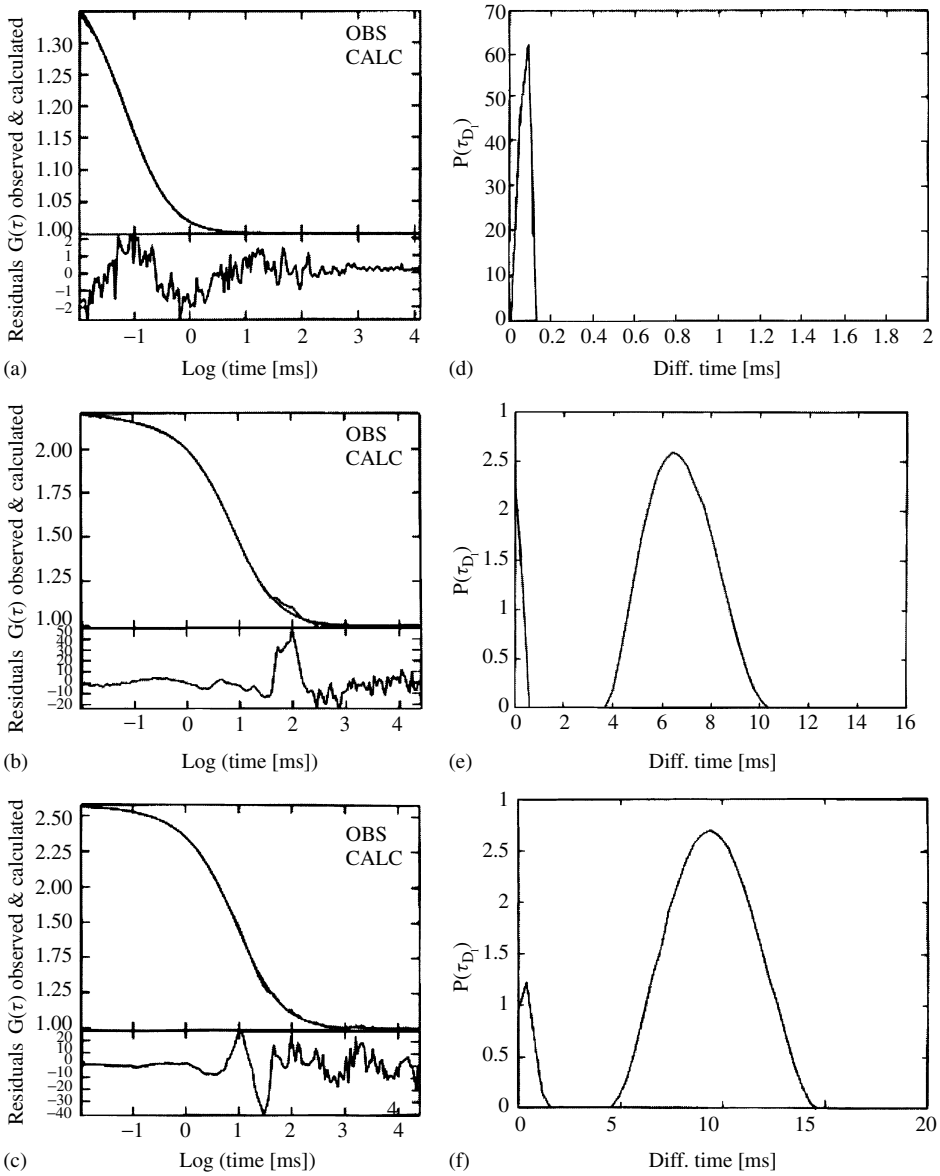

Fig. 8 The intensity autocorrelation function $G(\tau)$ of vesicles. (a) $G(\tau)$ of free rhodamine in solution; $\tau_D = 0.063$ ms. (b) $G(\tau)$ of rhodamine entrapped vesicles (REV), $\tau_D = 7.5$ ms; (c) $G(\tau)$ of rhodamine-labeled phospholipid vesicles (RLV), $\tau_D = 9.1$ ms; (d), (e), and (f) are the CONTIN distributions of diffusion times $P(\tau_{D_i})$ from (a), (b), and (c) respectively.

according to a model of multiple components (Fig. 8d–f). Owing to differences in diffusion times between free rhodamine and vesicles, it is possible to quantify the fractions of free rhodamine and vesicles; for example, in the ligand–receptor interaction studies, there is no need for a separation step for this quantification. The results demonstrate that melittin and magainin interact with phospholipid vesicle membranes in different ways. Melittin makes channels into vesicle membranes (Fig. 9, model I) as exposure of melittin to vesicles causes rhodamine to release only from REV but not from RLV. It is obvious that rhodamine cannot be released from RLV because the inside of RLV is free of dye molecules. In contrast, magainin breaks vesicle membranes (Fig. 9, model II) since addition of magainin to vesicles results in rhodamine release from both REV and RLV. As the inside of RLV is free of rhodamine, the appearance of rhodamine in solution confirms that these vesicles are broken into rhodamine-labeled phospholipid fragments after addition of magainin. This study illustrates several attractive features of the FCS technique for protein/peptide studies including vesicles. FCS is a sensitive and rapid technique to study molecular interactions of biologically important substances with vesicles. It

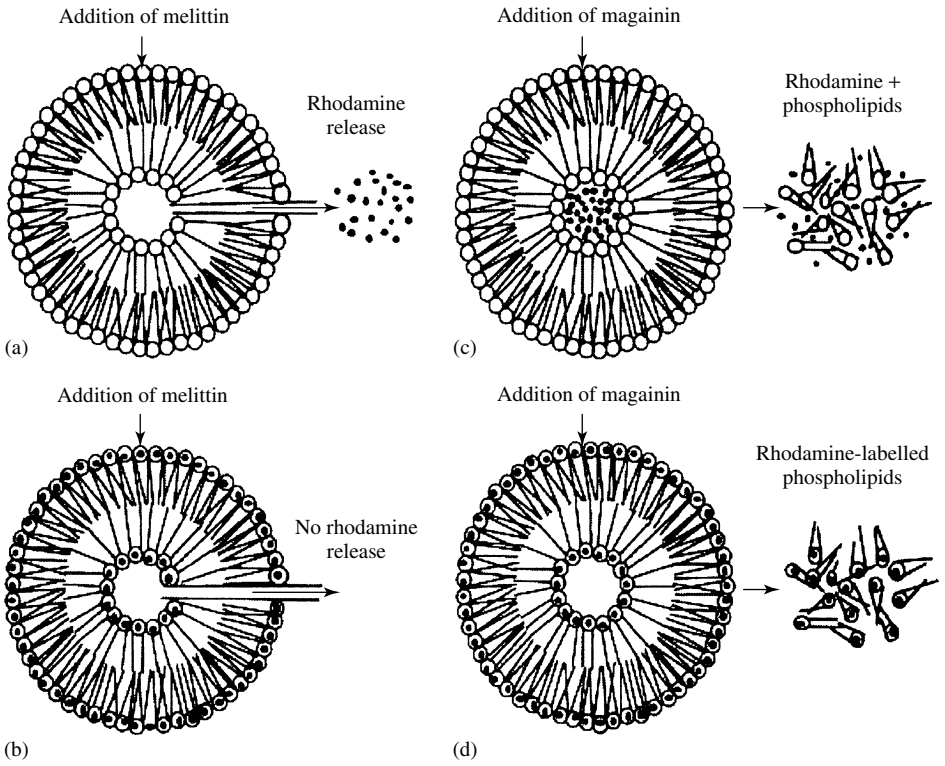

Fig. 9 Models for the peptide interactions with vesicles. Model I: Melittin makes channels into phospholipid vesicle membranes. (a) REV plus melittin; (b) RLV plus melittin; Model II: Magainin breaks phospholipid vesicle membranes; (c) REV plus magainin. (d) RLV plus magainin.

indicates that FCS can be used as a rapid protocol to test incorporation and release of drugs by vesicles, which is of pharmaceutical significance. It also provides a general idea of how FCS could be used to study molecular interactions of many other physiologically important peptides and proteins in vesicle membranes.

4.4 Protein–DNA Interactions

Binding of proteins (transcription factors) to DNA molecules plays key roles in assembling active transcription complexes. Generally, biochemical methods are used to study interactions between transcription factors and DNA molecules. Recently, protein–DNA interactions have been studied using biophysical methods such as NMR and FCS. It is important to mention that in certain cases, earlier data obtained by biochemical methods are inconsistent with those obtained by NMR and FCS with respect to the specificity and mechanisms of protein–DNA interactions. Here is an example of how FCS has been applied to study the interaction of the p53 protein (transcription factor) with DNA on the basis of the concept as given by Eqs. (15–17) (Sect. 3.3). The p53 protein is a sequence-specific transcription factor that plays a central role in cancer surveillance. p53 is a latent transcription factor that is activated by various forms of cellular stress including DNA damage. The p53 activation and consequently, p53-dependent transcription is controlled by the negative regulatory region in the CTD (C-terminal domain) of p53. Data on the p53 activation and its interactions with DNA as characterized by FCS demonstrate that a crucial mechanism by which p53 transcription function is regulated appears to operate through control of its DNA-binding properties. These FCS data present a two binding site mechanism, which postulates that p53 is not a latent DNA-binding factor but is involved in multiple interactions with DNA via its core and C-terminal domains. Thus, the earlier proposed allosteric and steric mechanisms of the p53 activation for binding to DNA are inconsistent with data obtained by FCS. Similar studies have been performed using capillary electrophoresis-single molecule FCS, and by fluorescence fluctuation spectroscopy. These examples provide a general idea of how FCS can be used to study specific interactions of various proteins with DNA. Regarding transcription factors, the FCS technique can offer a useful tool to study their interactions with DNA with reference to the specificity and mechanisms of interactions. In comparison with biochemical methods, FCS is not only fast and economic but also very specific. It is very likely that protein–DNA interaction with FCS can be performed in microchips. The most important perspective of protein–DNA assays with FCS is to study protein–DNA interactions at expression level in living cells.

4.5 DNA–DNA Interaction (DNA Sequencing)

Nucleic acid analysis plays a key role in understanding various biological processes. Generally, hybridization methods are used in order to detect specific DNA and RNA sequences, in which a specific probe (oligonucleotide, DNA, RNA) recognizes its complementary sequence in the target DNA and/or RNA. Traditionally, electrophoresis or liquid chromatography techniques are applied to analyze hybridization

reactions. However, these techniques have drawbacks as electrophoretic separations in agarose and polyacrylamide gel produce very poor resolution and possess lower sensitivity for long natural DNAs. With FCS, a higher sensitivity can be offered to detect DNA sequences using fluorescently labeled probes. For example, it has been described in detail how fluorescently labeled DNA oligonucleotides (19mer–23mer) have been used as probes for the HIV virus target RNA. The most important point is that FCS allows detecting and quantifying hybridization products without the need for bound–free physical separation by gel electrophoresis, filters, or column chromatography. As in the preceding examples, the separation by FCS is based on significant differences in diffusion times between the free and bound dye-oligonucleotides. The approach has also been described for multicomponent analysis using a combination of capillary electrophoresis and FCS. There are a number of publications concerning the fluorescence-based amplification at high template concentrations. As is known, the amplification of initially low copy numbers of templates is a general problem. Detection of DNA target sequences at the single-copy level without amplification can obviously overcome such limitations, which can result in nonspecific amplification at initially very low template numbers, for example, PCR (polymerase chain reaction). The major problem is that in nonspecific modes of detection, there is no guarantee that the specific target is available or that the correct sequence of the specific target amplification is produced in the amplification process. For DNA–DNA interactions of this kind, the two color cross-correlated FCS is a useful approach (Eqs. 22, 23(a–c), Sect. 3.5). In nucleic acid analysis by cross-correlated FCS, two oligonucleotide probes are fluorescently labeled in two different colors (each probe carries one color). These two fluorescently labeled oligonucleotide probes can be hybridized to a complementary target gene (DNA) such that both oligonucleotides bind to the same target at different sites. If the target is present in the sample, those probe molecules that bind to the same target are correlated to each other, in contrast to those probe molecules that do not bind to the same target. Even if there is a prominent excess of molecules in one color, the DNA carrying both probes on the same molecule can often be distinguished in a cross-correlation procedure. Two color cross-correlation FCS has been shown to be a specific mode of detection where the correct amplification product is identified and quantified. Two color cross-correlation FCS (and other cross-correlation/coincidence analyses based on similar approaches using ultrasensitive fluorescence techniques) can be useful for assays in microchips in order to screen for clinically relevant pathogens.

4.6 Monitoring of Molecular Processes in the Fast Time Range ($<\tau_D$) (Chemical Reactions, Photophysics, Conformational Changes)

For reactions that generate prominent fluorescence changes in the fluorescently marked molecules under study, and which are faster than the typical passage times (τ_D) of these molecules through the detection volume, the approach outlined in Sect. 3.4 is applicable.

Reactions that can be monitored include a range of chemical reactions, conformational kinetics, and transitions between different transient photophysical states of the fluorophores themselves.

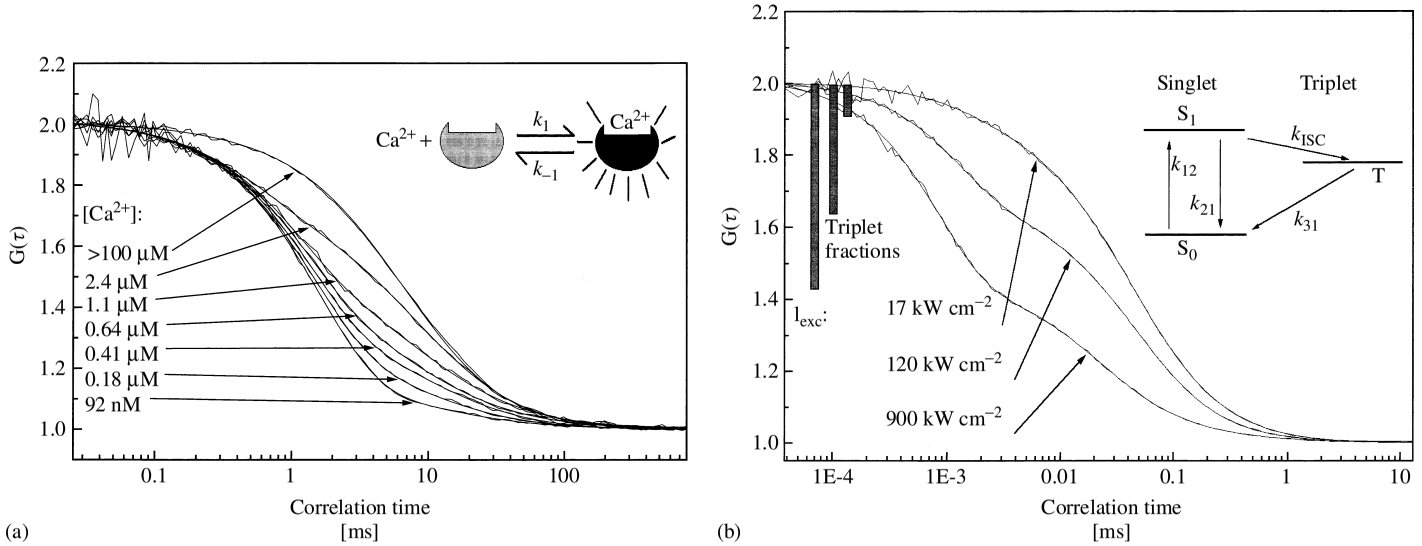

Fig. 10 (a) Experimental example of a reaction process that in an FCS experiment can be described by (Eqs. 18–21). Here, the association and dissociation of Ca^{2+} to the calcium-sensitive dye Rhod-II (Molecular Probes, Eugene, Oregon, USA) were followed. While almost nonfluorescent without calcium bound to it, the fluorescence brightness of the dye increases promptly upon binding to calcium. Here, the observation volume was deliberately expanded in order to make the passage times of the Rhod-II molecules long enough to exceed the relaxation time of the binding process to calcium. (b) Three correlation curves of the dye Rhodamine 6G in water with the total amplitudes normalized to 1. The FCS curves show two relaxation processes that are due to diffusion (slower) and singlet–triplet transitions (faster). With reference to (Eqs. 18–21), the processes correspond to $G_D(\tau)$ and $X(\tau)$, respectively, and the reaction matrix $\sum_{j,k=1}^{M} T_{jk}$ is given by the rate coefficients in the three-level reaction scheme enclosed in the graph with $M = 3$. With the normalization used, the amplitude of the fast process of the curves corresponds to the fraction of dye molecules in the detection volume that are in their triplet states. With increasing excitation intensities, this fraction is increased. The relaxation rate of the faster process corresponds to the relaxation time of the reaction scheme of the singlet–triplet transitions (inset), and increases from k_{31} (triplet deactivation rate) towards $k_{31} + k_{ISC}$ (sum of k_{31} and rate of intersystem crossing) with increasing excitation intensities.

A simple example of a chemical reaction monitored by FCS using this strategy is given in Fig. 10(a), where the fluorescence fluctuations in a calcium-sensitive fluorophore upon binding and dissociation of a calcium ion can be used to determine the calcium concentration in absolute terms as well as the local buffering properties. The same approach also applies to other ion-sensitive dyes, for instance, pH-sensitive dyes.

In Fig. 10(b), it is shown how FCS and the above approach provide a simple and convenient means to determine triplet state properties of fluorophores, offering a strong alternative to flash photolysis and other relaxation approaches. A wide range of photophysical states can be analyzed in a similar fashion, including charge transfer and trans–cis isomerization processes. The relative ease of measurement and the strong environmental sensitivity of these relatively long-lived photophysical states opens for microenvironmental monitoring applications where relatively small changes in the rates to or from these states owing to local environment influences can be followed.

Conformational kinetics of molecules can be followed via FCS if the fluorescence intensity of the fluorophore labeled to the molecule of interest clearly depends on its conformational state. The fluorescence can either be made sensitive to intramolecular distances, that is, between the fluorescent marker and some attached quencher molecule, or via fluorescence resonance energy transfer (FRET) between a donor and an acceptor fluorophore attached to the molecule of interest. Alternatively, the fluorescence is changed because of a conformation-dependent accessibility of quencher molecules to the labeling site of the fluorophore molecule.

4.7 FCS and Related Techniques in Drug Screening

A very important activity for generating new substances with therapeutic activity is the screening of compounds, which is based on their affinity to, or molecular interactions with certain target compounds. Functional genomics has resulted in the knowledge of a growing number of potential therapeutic targets. At the same time, combinatorial chemical synthesis techniques have enabled a rapid development of large compound libraries. Following this progress, the demand is stronger than ever for high throughput screening (HTS) technologies that can screen these potential therapeutic targets against large compound collections. This has stimulated technology development in the areas of assay automation, miniaturization, and detection technologies. Homogeneous assays, in which measurement can take place directly after mixture (''mix and measure''), without any filtration, separation, or washing steps in between, are well suited for HTS as they make the screening less time-consuming and labor-intense, and thus easier to automate. Miniaturization reduces the amount of biological and chemical reagents used per assay, and can facilitate higher throughput assay formats by enabling the use of parallel sample processing. Miniaturization, in turn, puts high demands on the sensitivity of the detection techniques used in the screening procedure.

Fluorescence-based detection methods can offer an outstanding sensitivity, and there is a strong trend towards using fluorescence as a readout mean in favor of, for example, radioactivity. Already some years ago, a strong interest from the pharmaceutical industry was focused on FCS

as a readout tool for HTS. This interest stemmed from several attractive features of the FCS technique as a HTS readout technique: (1) a sensitivity that enables detection at the level of single molecules; (2) small detection and sample volumes that strongly facilitate miniaturization; (3) lack of need for a physical separation of interacting from noninteracting molecules prior to measurement, which makes it possible to perform homogeneous assays; (4) reasonably fast readout times. Further, as indicated by previous studies (see Sect. 4.2), FCS can provide the possibility to identify and discover new target molecules on cell surfaces that has not been possible to detect by conventional methods. This flexibility in the choice of measurement medium thus makes it possible not only to perform HTS *in vitro* but also may open for HTS on a cellular basis.

The ability to distinguish two different particles in solution (e.g. bound and unbound ligands), which is essential in HTS, is typically based on differences in diffusion speeds in FCS. However, it should be pointed out that to resolve, for example, binding of a ligand to a receptor, their diffusion times through the detection volume need to differ quite substantially, since the diffusion constant is only approximately inversely proportional to the cubic root of the molecular weight (see also discussion in Sect. 4.1). The smaller the difference in diffusion speeds, the longer the measurement time needed to separate the species. Therefore, to reach short enough measurement times for HTS with FCS (of the order 1s), large differences in diffusion times between the free and bound species are required.

In view of this, FIDA/PCH (Sect. 3.8) offers a strong complementary analysis approach in HTS to time correlation analysis and FCS, providing a complementary set of readout parameters. In its basic version, the discrimination between species is based on differences in molecular brightness, and already a difference of 25% can allow two different species to be separated in the analysis, independent of the molecular mass, also allowing a faster readout. On the basis of FIDA/PCH assays can be designed in different ways such that the molecular brightness changes because of molecular interaction, either due to a change in environment or due to an energy transfer from one (donor) fluorophore to another (acceptor) fluorophore, or via changes in stoichiometry of fluorophore molecules present on the single particles.

HTS requires fast readout times and at the same time enough information from the sample to judge if, for example, a ligand has bound to a target molecule. Therefore, it is essential to maximize the number of fluorescence photons extracted from the molecules investigated during the readout time. Photophysical aspects are very important for practically all fluorescence spectroscopy techniques in which a high sensitivity or a fast readout is required. Since for HTS, both these properties are needed, this issue becomes of even greater importance. To optimize sensitivity and readout speed, additional strategies can be used. One useful strategy is to take advantage of several spectroscopic parameters, analyzing data from more than one output channel. In line with this strategy, the FIDA technique has been extended to also include lifetime, polarization, and emission wavelength ranges of the emitted fluorescence (Sect. 3.8). In this way, the global analysis of several signal parameters (from a combination of FCS and FIDA approaches) can significantly improve the probability for accurate molecular classification in compound screening. A further boost to the capacity would result from the

use of a parallel confocal optic readout. In combination with assay methods, proper liquid handling and robotics, as well as process flow and information management, ultrasensitive fluorescence detection techniques seem to be able to take HTS to new capacity levels. Assay systems that were capable of screening at their best thousands of compounds per day in the mid-1990s now transform into methods that are believed to be capable of 100 000 samples per day (so-called ultra-HTS (uHTS) methods).

5 Additional Remarks and Conclusions

Local fluctuations, reflecting intrinsic thermodynamic properties of a physical system in equilibrium, are usually a source of unavoidable noise in conventional ensemble experiments. FCS converts the thermodynamic noise into a very rich source of information about dynamic processes on the molecular scale. This is done by a combination of ultrasensitive fluorescence detection, providing the appropriate sensitive molecular indicator and a processing of the detected fluorescence data based on autocorrelation analysis. Autocorrelation analysis can, in a powerful way, select for correlated events on a molecular scale that reflects average properties of the molecules within an ensemble. In this chapter, we have illustrated how FCS and modalities thereof can be used to investigate a wide diversity of molecular phenomena taking place over a huge span of time-ranges.

FCS is excellently suited to retrieve temporal information about dynamic processes buried in a stochastic signal of an ensemble of molecules. Like in single molecule detection (SMD) experiments, where molecules are analyzed one by one, no synchronization by some external perturbation of the molecules is necessary to obtain this information. However, by detection and analysis of molecules one by one, and by the subsequent sorting of the molecules into frequency histograms based on their detected parameters, it is possible to reveal and characterize subpopulations to a greater extent than what is possible with FCS. On the other hand, the need in SMD for individual detection of the molecules makes the accumulation of a statistically sufficient amount of data slower than in FCS and related techniques. Moreover, at concentrations low enough for the measurement volume to harbor only one fluorescent molecule of interest at a time, many biological binding reactions and other forms of chemical reactions are very inefficient, if detectable at all. Owing to the lower concentrations of fluorescently marked molecules required, SMD approaches are also more sensitive to background light, which restricts the range of environments where they can be applied. Clearly, in terms of the conditions under which it can be applied, the information that can be derived, and the speed with which a statistically significant amount of data can be collected, FCS provides a bridge between conventional ensemble measurements and SMD-based approaches.

In FCS as well as in practically all SMD-approaches based on fluorescence detection, it is vital to maximize the number of detected fluorescence photons per molecule in order to obtain maximal information. Photobleaching and saturation of fluorescence set the ultimate limits. However, the information available from an FCS experiment can also be increased by taking advantage of the full information content of the detected fluorescence photons. In FCS, the temporal information of various dynamic processes can be used to determine concentrations of

reactants and reaction products, without the introduction of any physical separation steps. However, depending on the particular system under study, the determination of the concentration of the different reaction partners can sometimes be more easily determined by the use of an alternative way of data processing. In FIDA/PCH, the experimental conditions and the fluorescence raw data are identical, but the data is analyzed differently, with respect to intensity distributions, providing complementary information to FCS analysis. This illustrates the power and importance of an appropriate data processing of the fluorescence raw data, adapted to the system under study and the information sought. Yet another strategy is to take advantage of the additional properties of the detected fluorescence that can be registered in parallel with the fluorescence intensity (emission wavelength, polarization, fluorescence lifetime etc.). Spectral and spatial cross-correlation modalities of FCS, or the introduction of polarizers in front of the detectors to measure rotational diffusion, are examples thereof. When two or more measured parameter values, either of two different parameters in the same measurement or parameters from different measurements, can be expressed as a function of a common parameter, global analysis provides another data processing means to increase the accuracy of the parameter determination.

The drastic improvement in the sensitivity of the FCS instrumentation and the subsequent development of the FCS technique in the last decade illustrates how important the detected information content per molecule is for the overall performance of the method. FCS at its present stage has already found a wide application in biomedical research as a tool to investigate chemical reactions, in particular binding reactions in solutions and on cell surfaces. Clearly, the limits of the technique will be pushed further. The major challenges lie in extending the limits set by photophysical constraints, including the search for photochemically and photophysically more stable dyes, to take full advantage of the information content of the detected fluorescence and to optimally process the registered data, as well as to extend the possible environments where measurements can be performed. Of particular biomedical interest is to be able to more extensively investigate dynamic processes in intracellular environments. Here, FCS and related techniques are likely to be more successful than true SMD approaches because of the high background levels experienced inside cells, generated from light scattering and autofluorescence.

From the examples given, one can conclude that FCS offers a powerful tool for examining molecular interactions of biological importance with very high specificity, providing a fast and specific analysis for several important biological processes with high sensitivity. Thus, FCS can be used as a highly sensitive and specific assay to identify potential inhibitors for the aggregation process, involved in Alzheimer's and prion diseases, and to detect receptors in live cells, even if the receptors are present only in very sparse numbers. FCS can also be used as a rapid protocol to test incorporation and release of drugs by vesicles, which is of pharmaceutical significance. A very important perspective for the future of protein–DNA assays with FCS is to study protein–DNA interactions at expression level in living cells. Finally, two color cross-correlation FCS can be useful for assays in microchips in order to screen for clinically relevant pathogens.

Keywords

Excited State
The energy level a molecule reaches subsequent to the absorption of light, which is characterized by a different distribution of electron density compared to the ground (nonexcited) state of the molecule.

Fluorophore
A molecule that exhibits the property of fluorescence.

Stokes Shift
The difference in the wavelengths corresponding to the maxima of a fluorophore's absorption and emission.

Monochromator
An optical device that spatially separates electromagnetic radiation and hence allows for the isolation of a particular wavelength band.

Photomultiplier
An electronic device with a light-sensitive component that can convert light energy into an electrical signal and that can greatly amplify (multiply) the original photon energy.

Polarizer
An optical component that selectively transmits one direction of the electric field oscillation.

FRET
Fluorescence resonance energy transfer – the process by which the excited-state energy of a fluorophore (the donor) is transferred via a nonradiative process to another molecule (the acceptor).

FCS
Fluorescence correlation spectroscopy – a method that measures fluctuations in the fluorescence signal from a small sample volume and uses this data to gain information on diverse molecular parameters.

FISH
Fluorescence *in situ* hybridization – a method that utilizes fluorescently labeled nucleic acids sequences that hybridize to complementary sequences in cells, thus permitting their localization.

Fluorescence is the light emitted by an atom or molecule after a finite duration (typically on the order of nanoseconds) subsequent to the absorption of electromagnetic energy. Specifically, the emitted light arises from the transition of the excited species from its first excited electronic singlet level to its ground electronic level, and is usually (but not always) at longer wavelengths than the absorbed light. The development of highly sophisticated fluorescent probe chemistries, new laser and microscopy approaches, and site-directed mutagenesis has led to many novel applications of fluorescence in the chemical, physical, and life sciences. Fluorescence methodologies are now widely used in the biochemical and biophysical areas, in clinical chemistry and diagnostics, and in cell and molecular biology.

1 Introduction

Luminescent substances give rise to the emission of light after absorption of energy from an outside source. The most common source of this energy is light itself (photoexcited luminescence), although light emission following heating (thermal luminescence), chemical reactions *in vitro* (chemiluminescence) or *in vivo* (bioluminescence), or interaction with high-energy particles are also well known and have been extensively studied. In this article, we shall be concerned only with *fluorescence*, a process that occurs after photoexcitation. Moreover, we shall limit our discussion to fluorescence from molecules, as opposed to fluorescence from atoms.

2 Historical Overview

The first reported observation of fluorescence was that from a water infusion of the wood from a small Mexican tree, *Lignum nephriticum*. This wood was very popular in sixteenth to seventeenth century Europe, where it was known as *Lignum nephriticum* (kidney wood), because of its medicinal virtues for treating kidney affections. In 1565, Nicolás Monardes described a bluish opalescence from this infusion. These enigmatic optical properties eventually attracted the attention of several prominent scientists, including Athanasius Kircher, Isaac Newton, and Robert Boyle. The actual term *fluorescence* was coined in 1853 by Sir George Gabriel Stokes, whose seminal contributions helped systematize the study of light emission. Stokes clearly enunciated the fact that the fluorescent light was of longer wavelength than the exciting light – this wavelength difference between excitation and emission is now known as the *Stokes Shift*. Stokes' work led to a surge of qualitative studies on plant and animal extracts.

The theoretical foundations of modern quantitative fluorescence spectroscopy were established in the first half of the twentieth century by pioneers including Enrique Gaviola, Jean and Francis Perrin (father and son), Peter Pringsheim, Sergei Vavilov, F. Weigert, F. Dushinsky, Alexander Jabłoński, Theodor Förster, and more recently, Gregorio Weber. During this time, important concepts were introduced such as the excited-state lifetime, the polarization of the fluorescence, the quantum yield of

the emission process, and nonradiative energy transfer.

3 Basic Fluorescence Processes

Fluorescence occurs when a molecule (or atom) absorbs light and – after a finite interval usually on the order of nanoseconds – emits light, usually of lower energy. This phenomenon is illustrated in Fig. 1, which shows solutions of several different fluorophores illuminated by a UV hand lamp. Several aspects of the fluorescence phenomenon make it an extremely useful technique for investigations of molecular processes. Perhaps the most salient feature is the fact that the excited state persists for a duration in the range of nanoseconds, that is, some billionths of a second. Then, in essence, the excited fluorophore is like a molecular stopwatch that starts with the absorption of light and stops with the emission of light. The fluorophore thus provides a probe of events that occur on the nanosecond timescale. Observation of fluorescence requires an excitation source and a detector. In the simplest cases – as in the very early studies – these may correspond to sunlight and the eye. Presently, however, the availability of light sources providing radiation over a wide range of energies, encompassing the ultraviolet to the infrared, and of photodetectors with wide wavelength ranges, very high sensitivity (to the level of single photon detection), and ultrafast response times has greatly expanded the potential of fluorescence methods and has established their role in the chemical, physical, and life sciences.

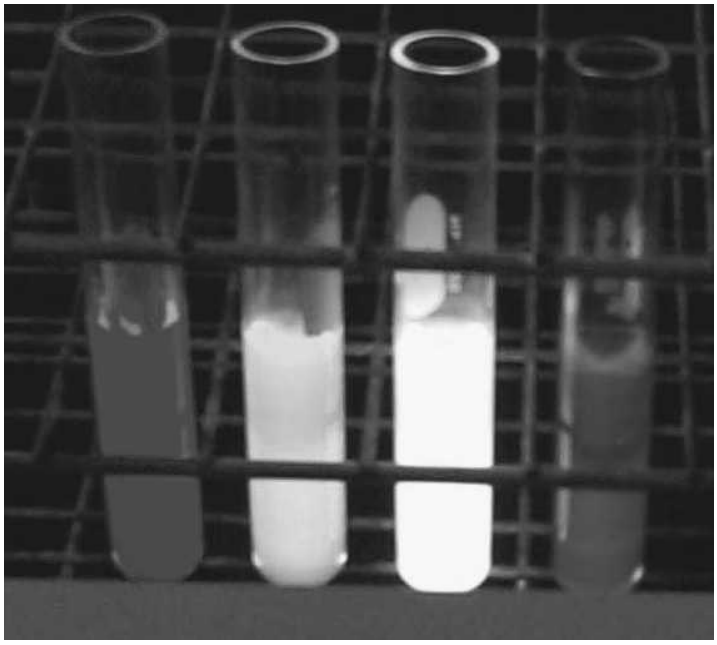

Fig. 1 Solutions of quinine sulfate, fluorescein, rhodamine, and ethidium bromide (from left to right) illuminated by the 365-nm line of a UV hand lamp.

Virtually all fluorescence data required for any research project will fall into one of the following categories:

1. fluorescence emission spectrum;
2. excitation spectrum of the fluorescence;
3. quantum yield;
4. fluorescence lifetime; and
5. polarization (anisotropy) of the emission.

Each of these categories will be discussed briefly since all of the special applications discussed later will utilize these parameters in one form or another. First, however, it is necessary to describe basic fluorescence instrumentation in more detail. To observe and record the fluorescence emission, we require an exciting source, as nearly monochromatic as possible, a monochromator to disperse the fluorescence emission, and a detector, usually a photomultiplier. The monochromatic excitation may be provided by a continuous light source such as a xenon arc (although laser sources that are intrinsically monochromatic may be used), and an additional monochromator. The plan of a typical spectrofluorimeter is shown in Fig. 2. Fluorescence measurements are almost

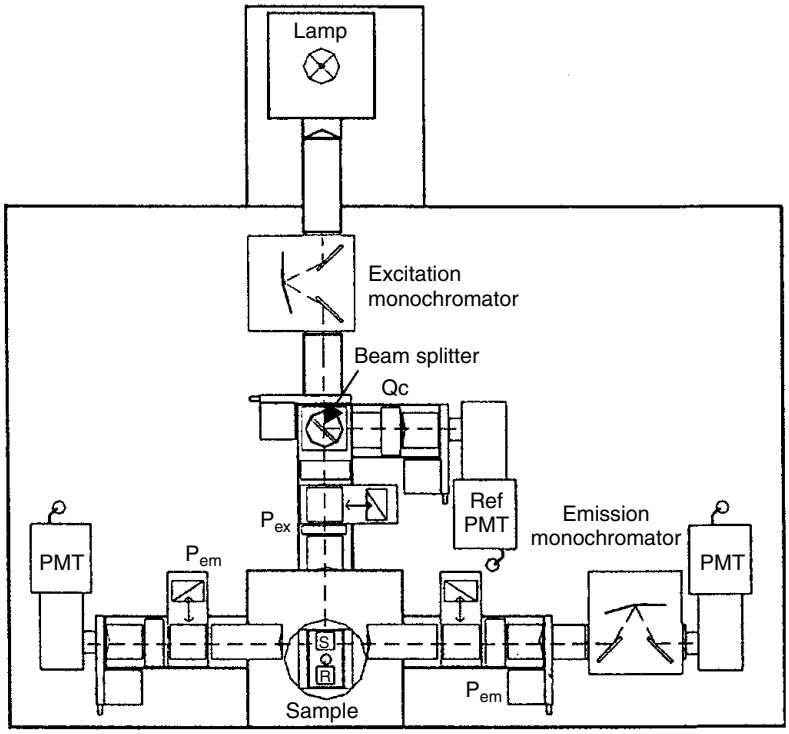

Fig. 2 Schematic representation diagram of a spectrofluorimeter indicating key components: revised with permission from commercial literature from ISS, Inc. The principal components include the xenon arc lamp, the excitation and emission monochromators, a quartz beam splitter, a quantum counting solution (Qc), three photomultiplier tubes (PMT) and excitation (P_{ex}) and emission (P_{em}) calcite prism polarizers.

always accomplished using a right-angle geometry, that is, the emission is detected in a direction 90° with respect to the excitation. This approach is used to reduce the level of exciting light reaching the detector side. All of the basic fluorescence measurements can also be made through a microscope and the quantitative use of fluorescence microscopy has increased tremendously in the last two decades. An in-depth discussion of the particular optics associated with fluorescence microscopes is beyond the scope of this article but the basic components of the spectrofluorimeter described above have counterparts in a fluorescence microscope.

3.1 The Fluorescence Emission Spectrum

In a typical emission spectrum, the excitation wavelength is fixed and the fluorescence intensity versus wavelength is obtained. A typical result is shown in Fig. 3(a) – which also depicts the absorption spectrum. The intensity axis of a fluorescence spectrum is usually reported in ''arbitrary units.'' This nomenclature recognizes the fact that the observed intensity depends not only on the concentration of the fluorophore and on molecular factors such as the fluorophore's extinction coefficient (a measure of a molecule's ability to absorb light energy at a particular wavelength) and quantum yield (*vide infra*), but also on instrumental factors such as the monochromator slit widths, the photomultiplier voltage, and amplifier gains. Fluorescence spectra recorded in this manner are ''technical'' or ''uncorrected'' emission spectra. Uncorrected spectra do not take into account the wavelength-dependent response of the emission optics (principally the monochromator) and the photodetector (most commonly a photomultiplier tube, although devices such as *avalanche photodiodes* are also becoming more common).

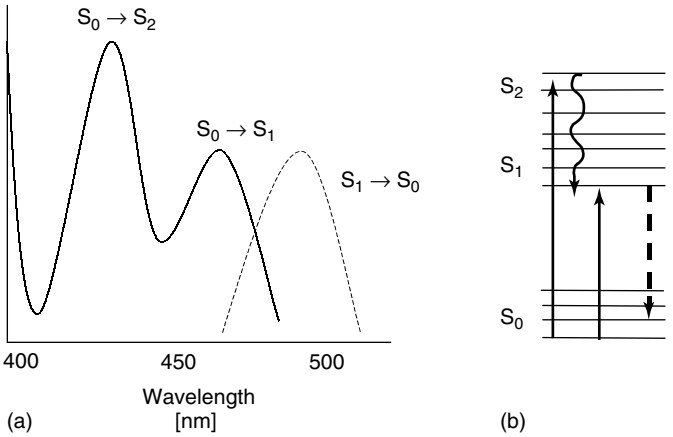

Fig. 3 (a) Schematic representation of the absorption (solid line) and emission (dotted line) spectrum of a fluorescent compound. (b) Perrin–Jabłoński Diagram. S_0 is the ground state while S_1 and S_2 are electronically excited states. The timescales of the absorption (solid up arrows), thermalization (thin squiggly down arrow) and emission (dotted down arrow) processes are typically in the range of $\sim 10^{-15}$, $\sim 10^{-12}$, and $\sim 10^{-9}$ s respectively.

Examination of a large number of emission spectra resulted in the formulation of certain general rules:

1. In a pure substance existing in solution in a unique form, the fluorescence spectrum is invariant, remaining the same independent of the excitation wavelength.
2. The fluorescence spectrum lies at longer wavelengths than the absorption (the Stokes shift).
3. The fluorescence spectrum is, to a good approximation, a mirror image of the absorption band of least frequency.

These general observations follow from consideration of the Perrin–Jabłoński diagram shown in Fig. 3(b). This diagram depicts the various electronic excited states that may be populated upon exposure of a fluorophore to light. Although the fluorophore may be excited into different singlet-state energy levels, which would correspond to excitation with different wavelengths, (e.g. S_1, S_2, etc.) rapid thermalization invariably occurs and emission almost always takes place from the lowest vibrational level of the first excited electronic state (S_1). This fact accounts for the independence of the emission spectrum from the excitation wavelength. The fact that ground-state fluorophores, at room temperature, are predominantly in the lowest vibrational level of the ground electronic state (as required from the Boltzmann's distribution law) accounts for the Stokes shift. Finally, the fact that the spacing of the energy levels in the vibrational manifolds of the ground state and first excited electronic states are usually similar accounts for the fact that the emission and absorption spectra (plotted in energy units such as reciprocal wave numbers) are approximately mirror images.

3.2 The Excitation Spectrum of the Fluorescence

The relative efficiencies of different wavelengths of incident light to excite fluorophores are represented by the excitation spectrum. In this case, the excitation is varied while the emission wavelength is kept constant. If the system is ''well-behaved'', that is, if the three general rules outlined above hold, one would expect that the excitation spectrum will match the absorption spectrum. Analogous to the ''corrected'' emission spectrum, the technical excitation spectrum must be corrected for the wavelength variation of the excitation source intensity.

3.3 Quantum Yield

The quantum yield (q) of a fluorophore is essentially a measure of how efficiently absorbed light is emitted. One way to view this quantity is $q =$ number of quanta emitted/number of quanta absorbed. The definition of the quantum yield and its first direct measurements were due to S. Vavilov in 1922, who discovered that fluorescein was an almost perfect emitter with a quantum yield close to unity. A more insightful expression relates the quantum yield to the relative rates of the radiative and nonradiative pathways, which deactivate the excited state. Hence,

$$q = \frac{k_r}{k_r + \sum k_{nr}} \tag{1}$$

where k_r and k_{nr} correspond to radiative and nonradiative processes respectively. In this equation, Σk_{nr} designates the sum of the rate constants for the various processes that compete with the emission

process. These processes include photochemical and dissociative processes in which the products are well-characterized chemical species (electron, proton, radical, molecular isomer) as well as less well-characterized changes that result in a return to the ground state with simultaneous dissipation of the energy of the excited state into heat (e.g. collisional quenching – *vide infra*). These latter processes are collectively called *nonradiative transitions* and two types have been clearly recognized: intersystem crossing and internal conversion. Intersystem crossing refers to the radiationless spin inversion of S_1 in the excited state that results in the isoenergetic, or almost isoenergetic, conversion into a triplet state. When spin inversion occurs in S_1, the resulting triplet reached is T_1, which is characterized by an energy intermediate between the ground state and the first excited singlet state. Another process that is nonradiative from the point of view of the original excited molecule is resonance energy transfer, which will be discussed later.

Molecules that decrease a fluorophore's quantum yield by direct interaction are often termed *quenchers*. Fluorescence quenching can result from interaction of the quenching molecule with the excited fluorophore – a process known as *collisional quenching* – or by formation of a ground-state complex between the quencher and the fluorophore. Both these quenching processes are usually reversible, as opposed to photobleaching of the excited fluorophore, which is usually (but not always) irreversible. Collisional quenching, which is also termed *dynamic quenching*, can be used to obtain information about the accessibility of the excited fluorophore to the solvent carrying the quencher. For example, the accessibilities of tryptophan residues in proteins can be accessed in this way; common quenchers used in such studies include iodide ions, acrylamide, and molecular oxygen. Dynamic quenching results in a decrease in both the fluorescence intensity and the excited-state lifetime. Static quenching, on the other hand, reduces the intensity but does not affect the excited-state lifetime, since the fluorophores that do not form a ground-state complex with the quencher will give rise to the same excited-state kinetics. The Stern–Volmer equation (below) is often used to describe simple quenching processes.

$$\frac{F_0}{F} = 1 + K_{SV}[Q] \qquad (2)$$

where F_0 and F are the fluorescence intensities observed in the absence and presence, respectively, of quencher, $[Q]$ is the quencher concentration and K_{SV} is the Stern–Volmer quenching constant. K_{SV} is equal to the product of k_q, the bimolecular quenching rate constant (proportional to the sum of the diffusion coefficients for fluorophore and quencher) and τ_0, the excited-state lifetime in the absence of quencher. In the case of purely dynamic quenching, $F_0/F = \tau_0/\tau$. If both static and dynamic quenching are occurring, then a modified Stern–Volmer equation may be applicable, for example,

$$\frac{F_0}{F} = (1 + k_q\tau_0[Q])(1 + K_a[Q]) \qquad (3)$$

where K_a is the association constant for the ground-state complex between quencher and fluorophore.

3.4 The Fluorescence Lifetime

The fluorescence lifetime is essentially a measure of the ''average'' duration of the excited state. Although we speak of

such properties as if they are studied in isolation, this is not usually the case. Emission processes are usually studied on *populations* of molecules and the properties of the supposed typical members of the population deduced from the macroscopic properties of the process (although recently, highly specialized instrumentation has been developed that permit, in favorable cases, the observation of emission processes from single molecules). Fluorescence lifetime measurements are traditionally realized using either the *impulse response* (time-domain) method, in which excitation is by a very brief pulse of light after which the direct decay of the fluorescence is observed, or the *harmonic response* (frequency-domain) method, in which the intensity of the excitation light is modulated sinusoidally and the phase shift of the fluorescence, relative to the excitation, is determined. Direct measurements of fluorescence lifetimes, using the harmonic response or phase method, were first successfully realized by the Argentinean, Enrique Gaviola in 1926. The first use of impulse methods to determine fluorescence lifetimes is generally credited to S.S. Brody in 1957. Since these early beginnings, both methods have advanced tremendously. Subnanosecond lifetimes can be routinely measured and these methods can also be applied through specially adapted fluorescence microscopes for *in vivo* cell studies. This method is known as *fluorescence lifetime imaging microscopy* (FLIM).

3.5 The Polarization (Anisotropy) of the Emission

Light can be considered as oscillations of an electromagnetic field perpendicular to the direction of propagation. Although both electric and magnetic components are present, we are usually concerned only with the electric field. In a typical polarization experiment, the sample is illuminated by monochromatic light through a polarizing device. A polarizer is an optical component, which selectively transmits one direction of the electric field oscillation. The most common polarizers used today are (1) dichroic devices, which operate by effectively absorbing one plane of polarization (e.g. Polaroid type-H sheets based on stretched polyvinyl alcohol impregnated with iodine); and (2) double refracting calcite ($CaCO_3$) crystal polarizers – which differentially disperse the two planes of polarization (examples of this class of polarizers are Nicol polarizers, Wollaston prisms, and Glan-type polarizers such as the Glan-Foucault, Glan-Thompson, and Glan-Taylor polarizers). If plane-polarized light of a particular electric vector orientation impinges on a sample, only those molecules that are properly oriented relative to this electric vector can absorb the light. Specifically, the probability of the absorption is proportional to the cosine squared of the angle θ between the exciting light and the molecule's absorption dipole ($\cos^2\theta$).

Hence, when we excite an ensemble of randomly oriented fluorophores with plane-polarized light, we are performing a *photoselection* process, creating a population of excited molecules that nominally have their excited dipoles lined up with the polarization direction of the excitation. If the fluorophore is excited into the lowest excited electronic state (the S_1 level shown in Fig. 3(b)), then the emitted light will usually be from a dipole oriented parallel to the absorption dipole.

As usually in fluorescence, the observation direction is at right angles to the excitation and the emitted light (suitably

isolated either with filters or a monochromator) is viewed through polarizers set to alternately pass the light, which is parallel or perpendicular to the laboratory axis (Fig. 4). Under these conditions, we can define the polarization function as shown in Fig. 4.

$$P = \frac{I_{||} - I_{\perp}}{I_{||} + I_{\perp}} \tag{4}$$

where P is the polarization and $I_{||}$ and $I_{\perp}$ are the parallel and perpendicular components, respectively, of the emission. If the fluorophore does not rotate during its excited-state lifetime (e.g. by being in a very viscous solvent or by being associated with a large macromolecule), then the emission will be polarized ($P > 0$), that is, the fluorescence intensity observed when the emission polarizer is oriented parallel to the vertical laboratory axis will exceed that observed when the emission polarizer is oriented perpendicular to the vertical laboratory axis. Note that an exception to this situation can occur when the fluorophore is excited into a higher electronic state (e.g. the S_2 level) if this energy level is characterized by an absorption dipole that is at a large angle relative to the emission dipole. In these cases, the observed polarization can be negative.

The analogous term anisotropy, usually denoted as r, is given by

$$r = \frac{I_{||} - I_{\perp}}{I_{||} + 2I_{\perp}} \tag{5}$$

In principle, the information content of the polarization and anisotropy functions are identical although there are practical circumstances that may argue in favor of one function over the other (e.g. the denominator in the anisotropy equation corresponds to the total intensity emitted from a sample excited with parallel polarized light and viewed at right angles). Polarization and anisotropy values can be readily converted via the equation

$$r = \frac{2P}{3 - P} \tag{6}$$

The essential aspect of fluorescence polarization, which makes it useful in the biomedical field, is that it provides information on the rotational mobility of a fluorescent molecule. In 1920, F. Weigert discovered that the fluorescence from solutions of dyes was polarized. He discovered that polarization increased with the size of

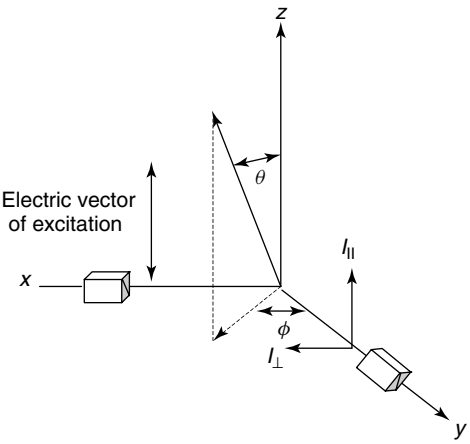

Fig. 4 Diagram depicting photoselection of an absorption dipole, making angles θ with the z-axis (in the x-z plane) and ϕ with the y-axis (in the x-y plane) by vertically polarized light and observation along the y-axis of the vertical (parallel) and horizontal (perpendicular) components of the emission through a polarizer. The rectangular boxes represent polarizers.

the dye molecule and the viscosity of the solvent, yet decreased as the temperature increased. He recognized that all of these considerations meant that fluorescence polarization increased as the mobility of the emitting species decreased. In 1925–1926, Francis Perrin (son of the famous French physicist, Jean Perrin), published several important papers describing a quantitative theory of fluorescence polarization: his famous equation, now known as the *Perrin equation*, contains most of the essential information that we use to this day and (in modern form) is given as

$$\frac{1}{p} - \frac{1}{3} = \left(\frac{1}{p_0} - \frac{1}{3}\right)\left(1 + \frac{RT}{V\eta}\tau\right) \quad (7)$$

where P is the observed polarization, P_0 is the limiting polarization (which is the polarization in the absence of rotation and which depends upon the relative orientation of the absorption and emission dipoles), R is the universal gas constant, T is the absolute temperature, V is the molar volume of the rotating unit, η is the solvent viscosity, and τ is the excited-state lifetime. This equation can be rewritten to have more direct application to the rotation of fluorescent molecules as

$$\frac{1}{p} - \frac{1}{3} = \left(\frac{1}{p_0} - \frac{1}{3}\right)\left(1 + \frac{3\tau}{\rho}\right) \quad (8)$$

where ρ is the Debye rotational relaxation time, which, for a sphere is given as

$$\rho_0 = \frac{3\eta V}{RT} \quad (9)$$

The limiting polarization, and hence the observable polarization, can vary between $+1/2$ and $-1/3$, depending upon the orientation of the emission dipole (the electric dipole on the nuclear framework, which exists during the excited state). Usually, though not always, excitation into the highest wavelength absorption band results in the highest possible limiting polarization. The rotational relaxation time of a molecule is the time it takes to rotate through an angle equal to the arccos of $1/e$ – which corresponds to $\sim 68.4^\circ$. (A quick and very approximate estimation of the Debye rotational relaxation time, in nanoseconds, of a molecule can be obtained by dividing the molecule's molecular weight by 1000 – e.g. a spherical protein of molecular weight 50 000 Da will have a Debye rotational relaxation time in the range of 50 ns). Hence, polarization measurements give direct information on the rotational mobility of a fluorophore and on any molecule attached to the probe.

The Perrin equation can be written in terms of anisotropy, limiting anisotropy (r_0) and rotational correlation time (τ_c) as

$$\frac{r_0}{r} = \left(1 + \frac{\tau}{\tau_c}\right) \quad (10)$$

where τ_c, the rotational correlation time is one-third the Debye rotational relaxation time.

Since the mobility of a fluorescence molecule will change upon binding to another molecule, one can utilize fluorescence polarization to study and quantify biomolecular interactions. Consequently, fluorescence polarization has been used for many years to study biochemical systems, such as protein–protein and protein–ligand interactions, membrane dynamics, and in recent years, protein–DNA and DNA–DNA interactions. In the last two decades, fluorescence polarization methods have also been increasingly used in medical diagnostics and high-throughput screening. One of the most widely used techniques in clinical assays for drugs or metabolites is the fluorescence polarization immunoassay (FPIA). In this method, the target molecule, which

is often but not always a drug or metabolite, is chemically linked to a fluorophore (the probe fluorescein is often used). In the presence of an antibody specific for the target molecule, the fluorophore-linked target will be bound to the antibody and its rotational mobility will be slow (relative to the fluorescence lifetime) and hence the emission will have a high polarization. When the appropriate sample is introduced, derived, for example, from blood or other fluids, the target molecule, if present, will bind to the antibody, displacing the fluorephore-linked target. Free in solution, this fluorophore-target molecule will have an increased rotational mobility (lower Debye rotational relaxation time) and hence a lower polarization. Hence, it is relatively straightforward to setup a standard curve relating the observed polarization to the concentration of the target molecule in the sample. The diagnostic field, in general, uses the unit known as *millipolarization* or ''mP'', which is the normal polarization times 1000; for example, a polarization of 0.200 corresponds to 200 mP units. Fluorescence plate-readers, which can measure both intensity and polarization, are now routinely used for high-throughput screening. At the time of this writing, fluorescence polarization plate-readers for 1536 wells are available – but one can expect that number to increase in the near future.

4 Multiphoton Fluorescence

As long ago as 1931, the famous physicist Maria Goeppert-Mayer predicted the possibility of nonlinear, multiphoton absorption. It was not until the 1990s, however, that the modern use of multiphoton fluorescence microscopy developed. If an excitation light density is sufficiently high, which can be achieved using ultrashort pulsed (femtosecond), high peak power (kilowatt) laser sources such as a Titanium : Sapphire laser (which emits in the near-infrared, over a range of around 700–1000 nm), then two photons, each at approximately half the wavelength of the normal (i.e. one photon) absorption of the target chromophore, can be simultaneously absorbed. The shape and position of a fluorophore's two-photon absorption cross-section can differ somewhat from that expected from the one-photon absorption spectrum. Multiphoton excitation, coupled with a fluorescence microscope, offers several advantages over traditional one-photon excitation, namely, (1) a very large separation between the excitation and emission wavelengths (which greatly minimizes problems associated with scattered light); (2) an intrinsic confocal aspect; and (3) reduced overall photobleaching, since light outside the focal region is at a wavelength not usually absorbed by the sample. Single- and two-photon excitation processes are depicted in Fig. 5(a). The sketch on the left side of Fig. 5(b) attempts to depict a typical light density profile generated by a microscope objective – one notes that exciting light, although maximal at the focal point, persists throughout a larger area, which means that fluorophores both above and below the focal plane are excited. Fluorescence from the focal plane can be preferentially isolated using traditional confocal optics. The drawing on the right side of Fig. 5(b) attempts to depict the fact that the two-photon light density is at a far longer wavelength than the one-photon case, such that the sample is essentially transparent to this wavelength, and also that the light density at the focal point is sufficiently high to generate the two-photon effect so that fluorophore

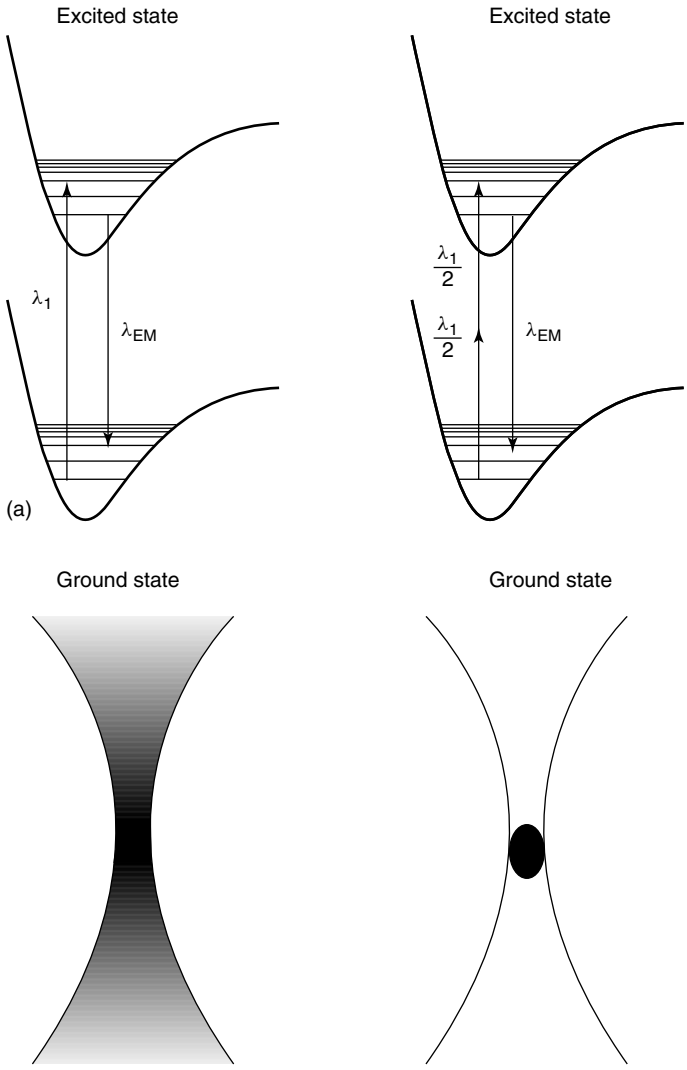

Fig. 5 Depiction of one- and two-photon absorption processes. (a) Energy level diagrams depicting (left) one-photon absorption and emission and (right) two-photon absorption and emission. (b) Depiction of effective excitation light energy in a volume element illuminated by a microscope objective for (left) one-photon and (right) two-photon processes.

excitation occurs only in a small volume near the focal point. Two-photon excitation is currently finding wide application in *in vivo* fluorescence microscopy.

5 Fluorescent Probes

Fluorescence probes can be broadly placed into two categories, namely, intrinsic probes and extrinsic probes. Intrinsic probes include any naturally occurring molecule that exhibits sufficient fluorescence to be of practical utility. Examples include the aromatic amino acids, especially tryptophan and tyrosine, NADH, FAD, FMN, some porphyrins, some fatty acids and lipids, some modified nucleic acids (such as the Wye base in some transfer RNAs), pyridoxal phosphate, chlorophylls, and pteridines. Extrinsic probes are those that can be introduced into the target system, either noncovalently or covalently. Up until the late 1970s, the choice of commercially available probes was quite limited – typically, researchers had to design and synthesize fluorophores for particular types of studies. The choice of fluorophore was dictated by the properties of the instruments (light sources and photomultiplier sensitivities) as well as by the lifetimes and spectral properties required. The first probe made for physicochemical studies of proteins was dimethylaminonaphthalene sulfonyl chloride (dansyl chloride), synthesized by Gregorio Weber around 1950 and designed to be conjugated to proteins and used for fluorescence polarization measurements. In the last two decades, however, the commercial availability of fluorescence has greatly expanded; thousands of fluorescence probes are now available. Examples of common noncovalent probes, which associate reversibly with various biomolecules are ANS, DPH, LAURDAN, ethidium bromide, Hoechst dyes, and DAPI, to name just a few. Covalent probes, on the other hand, are specifically functionalized with reactive groups such as sulfonyl chloride, isothiocyanate, succinimidyl ester, iodoacetamide, maleimide, hydrazine derivatives, azides, and others, to target a wide variety of functional groups in proteins, nucleic acids, carbohydrates, and lipids, including amine and carboxylic acid groups, thiol groups, hydroxyl groups, and so on. In addition to probes specifically designed to target biomolecules for solution studies, a wide range of probes exists, which are specialized for fluorescence microscopy studies on living cells. Such probes include a wide variety of ion-specific fluorophores that change one or more of their fluorescence properties (such as quantum yield, excitation or emission spectrum) upon binding ions including calcium, magnesium, zinc, sodium, potassium, or chloride, and hence can be used to follow alterations in the levels of such ions in living cells. Additionally, fluorescence studies on cells are often accomplished using fluorescently labeled antibodies targeted to specific cell constituents, chimeric proteins linked to green fluorescent proteins (GFP) (*vide infra*) or fluorophores that partition to specific cellular structures such as membranes, mitochondria, nuclei, and so on. An example of cells labeled with multiple fluorescent probes is illustrated in Fig. 6.

6 Green Fluorescent Proteins

The past decade has witnessed an explosion in the use of the family of naturally fluorescent proteins known as *green fluorescent proteins* or GFPs. GFP, a protein

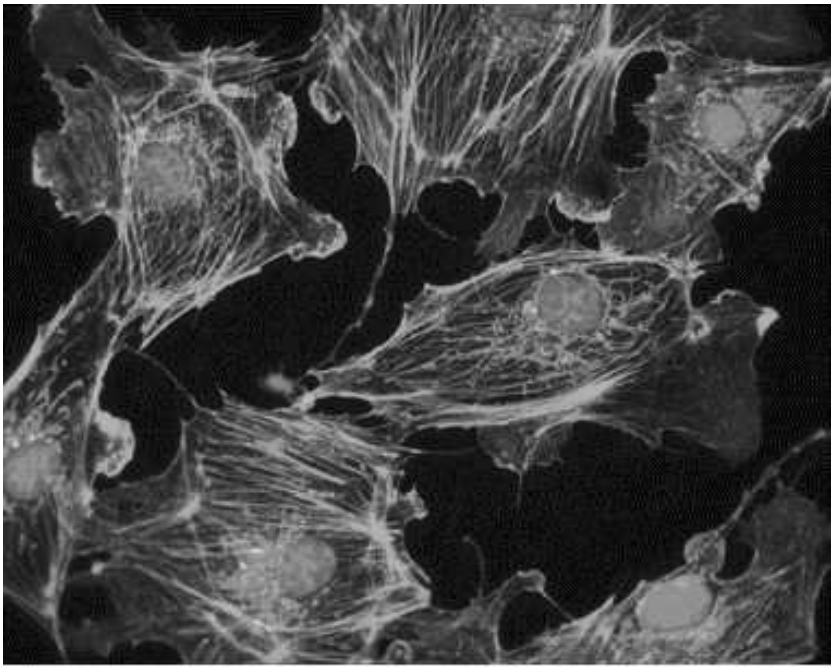

Fig. 6 Fluorescence microscope image (multiexposure) showing bovine pulmonary artery endothelial cells labeled with a red fluorescent dye that stains mitochondria in live cells, and then fixed, permeabilized, and stained with BODIPY FL phallacidin, a green fluorescent, high-affinity probe for F-actin, and DAPI, a probe that emits blue fluorescence upon binding to AT regions of DNA. Reproduced with permission from the Molecular Probes Image Gallery (copyright owned by Molecular Probes, Inc.) (see color plate p. xxv).

containing 128 amino acid residues, was originally isolated from the pacific northwest jellyfish *Aequorea victoria*. The fluorescence moiety in GFP, contained within a ß-sheet barrel, derives from autocatalytic and cyclization reactions involving three amino acid residues, namely, Ser65, Tyr66, and Gly67. This reaction is unusual and occurs only because of the unique environment offered by the overall GFP structure. The biological function of GFP is to absorb a photon emitted by Aequorin, a protein that catalyzes a chemiluminescence in the presence of calcium. By absorbing the blue photon (~470 nm) from the Aequorin complex and reemitting a green photon (~520 nm), GFP shifts the emission from the jellyfish to longer wavelengths, which presumably confers a biological advantage (for example, the green photon may be less prone to scattering processes as it traverses the ocean environment and hence conveys information over longer distances). In the 1990s, molecular biologists began to prepare *in vivo* chimeric proteins containing GFP (i.e. molecular biology techniques were used to link the DNA encoding for the protein of interest to the DNA encoding for GFP), which enabled observation of the chimeric proteins using fluorescent microscopy. It was soon found that alteration of the primary sequence of wild type GFP could result in GFP variants with diverse spectral properties

such as red- or blue-shifted emissions, higher quantum yields, and greatly improved photostability. These GFP mutants, sometimes denoted according to their colors such as yellow fluorescent protein (YFP), cyan fluorescent protein (CFP), or enhanced green fluorescent protein (EGFP), enable the tracking of multiple chimeric protein *in vivo* and can also serve as donors and acceptors in fluorescence resonance energy transfer (FRET) measurements (*vide infra*). Examples of mice carrying GFP-actin chimeras is shown in Fig. 7, which also demonstrates that the DNA encoding for the chimera is transmittable to new generations. More recently, other classes of intrinsically fluorescent proteins have been discovered in coral such as *Discosoma*, and in other organisms. A well-characterized example is the red fluorescent protein drFP593, more commonly known as DsRed. These proteins, like the GFP family, are able to generate a fluorescent moiety out of amino acids in the primary sequence. As the name suggests, the emission from these proteins is at longer wavelengths (red-shifted) relative to GFP.

7 FRET

Fluorescence resonance energy transfer (sometimes referred to as Förster resonance energy transfer in honor of Theodor Förster's contribution to the theory) is now widely utilized in both biochemistry and cell biology. The basic concept is that fluorescence molecules in their excited

Fig. 7 GFP mice (photograph reproduced with the permission of the University of Hawaii).

state can transfer the excited-state energy to a nearby acceptor molecule. Such FRET can be detected by a decrease in the quantum yield and lifetime of the donor fluorophore and an increase in the fluorescence of the acceptor (if the acceptor is a fluorophore). The rate of transfer, $k_T(r)$, is given by

$$k_T(r) = \frac{Q_D \kappa^2}{\tau_D r^6}\left(\frac{9000(\ln 10)}{128\pi^5 N n^4}\right) \times \int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 d\lambda \quad (11)$$

where Q_D is the quantum yield of the donor, τ_D is the donor lifetime in the absence of acceptor, r is the distance between donor and acceptor, N is Avogadro's number, n is the refractive index of the medium between donor and acceptor, $F_D(\lambda)$ is the fluorescence intensity of the donor in the wavelength range λ to $\lambda + \Delta\lambda$, $\varepsilon_A(\lambda)$ is the extinction coefficient of the acceptor at wavelength λ, and κ^2 is the "orientation factor," which is assumed to be 2/3 in the case of dynamic random averaging between donor and acceptor. Since the efficiency of energy transfer depends upon the inverse sixth power of distance between donor and acceptor, FRET methods provide a "spectroscopic ruler" for molecular systems. The utility of FRET ultimately depends on the so-called *critical transfer distance* between donor and acceptor, which is the distance at which 50% transfer will occur. This value is typically in the range of 10 Å to 100 Å and depends upon the specific characteristics of the donor and acceptor molecules, such as the extent of overlap between the donor fluorescence and the acceptor absorption. Although FRET methods are normally applied *in vitro* and often form the basis of diagnostic assays, recent advances in using site-directed mutagenesis to alter the absorption and fluorescence properties of GFP has enabled the development of *in vivo* FRET between donor and acceptor GFP variants.

8 Flow Cytometry

In flow cytometry, individual cells flow past an illuminator (almost always a laser source) and a detector and a large number of quantitative determinations, based both on light scattering and fluorescence, can be carried out simultaneously. The cells may be rendered fluorescent by the use of specific fluorophores, such as fluorophore-linked antibodies or fluorophores, which can be targeted to specific biomolecules such as DNA or membranes. The fluorescence can be detected and a variety of information can be ascertained. In addition to simply the presence or absence of a signal, modern instrumentation may carry out multiple, sophisticated fluorescence determinations, including time-resolved measurements. Analysis rates as high as 100 000 cells per second have been achieved. A wide variety of biochemical, immunological, and clinical applications of flow cytometry has been established. Quantitative determination of cellular DNA is one important application of the method since one can obtain a distribution histogram of the DNA content of thousands of cells, which offers information on both the cell cycle stage as well as the presence of aneuploid cells. Immunophenotyping is another important application. In addition to simple fluorescence determinations, a flow cytometry may be used to sort and separate cells – in this case, the approach is often referred to as *fluorescence-activated cell*

sorting (*FACS*). Operationally, an FACS instrument is essentially a specialized fluorescence microscope, which utilizes electrostatic deflection of charged droplets to sort cells. Living cells are aspirated from a sample and injected individually into a stream that eventually breaks down into droplets, which enter an illumination chamber. Here, a laser source impinges upon the droplet and if the cell has the appropriate fluorescence properties (arising, for example, from fluorophore-tagged antibodies, fluorophores targeted to DNA- or GFP-related probes), a charge will be applied to the droplet causing it to be deflected by high-voltage plates to a collection area. In this way, cell populations can be sorted and quantified.

9 FCS

Fluorescence correlation spectroscopy (FCS – sometimes referred to as fluctuation correlation spectroscopy) takes advantage of the fact that – at very low concentrations and in very small observation volumes – the number of molecules resident at any given time in the observation volume will fluctuate as molecules enter or leave the volume. By analyzing the temporal properties of this fluctuation, one can deduce various molecular properties, for example, the diffusion coefficient, which in turn can be related to the size and shape of the molecule and the viscosity of the environment (e.g. cell membranes or cytoplasm). This information, in turn, can often be related to the state of aggregation of the target molecule, both as regards self-association and association with other biomolecules (e.g. proteins, membranes, or nucleic acids). In modern instruments, the sample consisting of a fluorescence probe associated with the target molecule is placed in a fluorescent confocal microscope and is illuminated with a CW (continuous wave) laser. In some cases, an ultrafast laser pulse characterized by a high repetition rate and high peak power is used to generate multiphoton excitation (*vide supra*), which allows excitation in a very small sample volume (typically on the order of femtoliters). FCS can be applied both *in vitro* and *in vivo*.

10 FISH

Fluorescence *in situ* hybridization (FISH) is a method used to localize and quantify specific nucleic acid sequences. Typically, fluorescence probes are incorporated into short sequences of single- or double-stranded DNA or RNA, either by direct labeling of individual nucleotides followed by polymerization or by direct labeling of the nucleic acid polymers. These probes can then be introduced into a cell where they will bind to complementary nucleic acid sequences (in the case of double-stranded probes, a denaturation and hybridization step may be included). The location of these sequences in the cell can then be determined by high-resolution fluorescence microscopy. In addition to probes for specific short nucleic acid sequences, one can utilize libraries of probes to ''paint'' an entire chromosome and hence use the method for spectral karyotyping.

Bibliography 517
Primary Literature 517

Keywords

Emulsion
A thermodynamically unstable dispersion of micellar particles or globules in a liquid medium.

Foaming
A coarse dispersion of a gas in a protein matrix in which the bulk of the phase volume is the gas, with the matrix encasing the gas bubbles in thin sheets called *lamellae*, which are formed by agitating the protein matrix and gas together in the presence of a stabilizing agent.

Food Protein Interaction
The interaction of protein molecules and other compounds within their domain, which affects the proteins' behavior in food products.

Gelation
The formation of an ordered, continuous matrix entrapping another component, in which attractive and repulsive forces are balanced.

Hydrogen Bond
A highly directional bond in which a hydrogen atom is shared by two other atoms. One of the atoms is frequently covalently linked to that hydrogen atom.

Hydrophobic Interactions
Nonpolar molecules or groups tend to associate with one another in water and hold strong preference to nonpolar environments.

Phospholipids
Membrane lipids that possess polar groups linked to a diglyceride by a phosphodiester bridge.

Protein Micelle
Protein particles formed by colloidal association of protein monomers. The interaction is largely driven by the decrease in free energy resulting from hydrophobic attractions of nonpolar portions of the molecules.

Rheology
Normally refers to the flow and deformation of ''nonclassical'' materials such as rubber, molten plastics, polymer solutions, slurries and pastes, electrorheological fluids, blood,

muscle, composites, soils, and paints. These materials can exhibit varied and striking rheological properties that classical fluid mechanics and elasticity cannot describe.

Syneresis
Shrinking of the gel with expulsion of trapped liquid.

van der Waals Force
A nonspecific attractive force between atoms or molecules.

Proteins are the most abundant macromolecules found in living cells and approximate half of the cell's dry weight. They are required in the food of humans, fish, and most higher animals. Historically, food proteins have been selected for their nutritional value and can be obtained from a wide variety of naturally occurring sources. Proteins undergo a wide range of structural and conformational changes through a variety of complex interactions during processing and storage. Such changes can affect the principal purpose of dietary proteins, which is to supply nitrogen and amino acids for the synthesis of proteins in the body. It is through an understanding of these interactions and their effects on functionality that food proteins have played a major role in the food supply.

The macrostructure of a protein is primarily determined by its amino acid sequence. Amino acids are essential in basic nutrition, growth, and maintenance. Nine of the 20 identified amino acids, namely, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine, are considered essential. They are so classified because they cannot be synthesized by humans and must therefore be supplied in the diet. When essential amino acids are not supplied in sufficient quantity, they restrict the adequate utilization of other amino acids and are thus termed *limiting amino acids*.

The processing of food proteins is designed to reduce microbial and enzymatic spoilage, inactivate antinutritional substances, improve the availability of perishable foods, and enhance the sensory quality of the food. Chemical changes that occur during food processing can have a significant impact on the nutritional value, the sensory properties, as well as the general functionality of the food. Heat treatment of proteins under acidic conditions can result in denaturation or even total unfolding of proteins and inactivation of enzymes and antinutritional substances. More severe heating can cause proteins and/or enzymes to cross-link with one another. Process-induced chemical interaction can also occur between proteins and carbohydrates, which leads to nonoxidative, nonenzymatic browning (the Maillard reaction). Lipids, especially when unsaturated, are susceptible to oxidation. They can form lipid peroxides, which interact with proteins to yield lipid–protein complexes, thus decreasing the nutritional value of the food.

In addition to the above-mentioned purposes of food protein processing, proteins play an important role in improving the functionality of food ingredients. For instance, heat denaturation of whey proteins before spray-drying improves their

water-holding properties. Alkali treatment of soy proteins is used to improve their solubility and textural properties, and to obtain desirable rheological properties. Viscosity and solubility measurements are commonly used to obtain information about the functional behavior and physicochemical nature of proteins.

1 Protein Structure and Conformation

Proteins are natural compounds composed of amino acids organized at four different levels of structure: primary, secondary, tertiary, and quaternary. The primary structure consists of amino acids that are sequenced in a linear polypeptide chain and constitute the basic building blocks. Amino acids are joined together through an amide linkage or peptide bond, which is formed through the removal of a hydroxyl group from the carboxyl group of one amino acid and a hydrogen atom from the α-amino group of the adjoining amino acid. The C−N bond of the peptide linkage exhibits partial double-bond character and is not free to rotate, which imposes some constraints on the number of conformations that the polypeptide can assume (Fig. 1). There is, however, a large degree of rotational freedom around two single bonds $N-C_\alpha$ (φ) and $C_\alpha-C$ (ι) of the polypeptide.

The secondary structure of the polypeptide of the protein refers to the spatial arrangement of amino acid residues that are near one another in the amino acid sequence. It is frequently composed of α-helices, β-pleated sheets, and random coils, such as β-lactoglobulin (see Fig. 2), one of the major milk proteins. The α-helix structure exists in polypeptides that are tightly coiled into a rodlike structure with side chains extending outward from the helix. It is stabilized by strong hydrogen bonds between the NH and CO groups of the main chain. In contrast, a polypeptide chain in the β-pleated-sheet structure is almost fully extended. The β-pleated sheet is stabilized by hydrogen bonds between NH and CO groups in different peptide chains. The arrangement of member strands can be parallel, antiparallel, or a mixture of the two. Many proteins have various well-defined combinations of β-strands and α-helices. Some amino acids cannot form α-helices because of electrostatic repulsion or bulky side chains. As a result, the polypeptide assumes a random-coil structure having minimal electrostatic free energy. In general, regions of α-helices and β-sheets in the protein are well defined; random coils are not.

The tertiary structure refers to the steric relationships of amino acid residues that are far apart in the linear sequence and the overall architecture in three dimensions of the polypeptide chain whose folding brings into proximity parts of the molecule otherwise widely separated along the backbone. Proteins containing more than one polypeptide chain exhibit another level of organization. This quaternary structure describes the aggregation of the separate polypeptide chains of a protein, which is often stabilized by hydrogen bonds and van der Waals forces. Structural changes at this level have unique biological applications that are often mediated by enzymes. It is through systematic denaturation of the organized structures and forces of

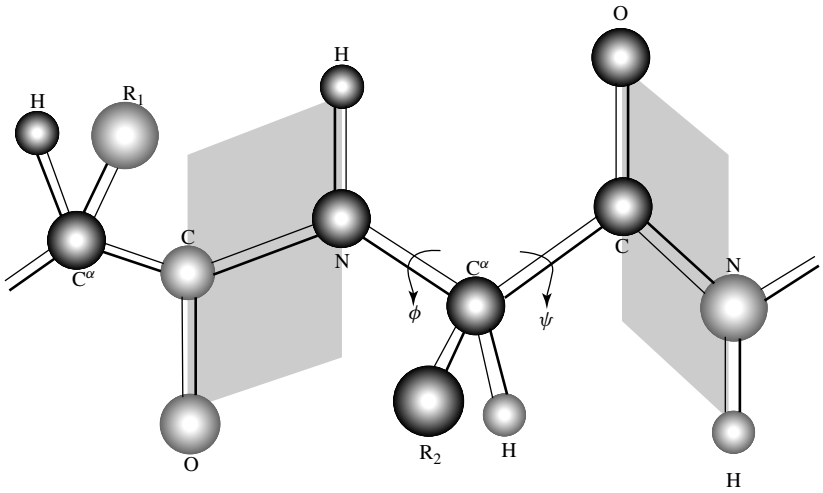

Fig. 1 Polypeptide chain linking two peptide units. The terms φ_ and ι refer to rotation about the α-carbon (C^{α}). The two peptide bonds adjacent to C^{α} are located in different planes.

Fig. 2 Three-dimensional crystal structure of bovine β-lactoglobulin (PDB code 1B8E). Helices and β-sheet strands are shown in ribbons and random coil is shown in tubes. The arrows on the ribbons represent the direction of β-sheet strands.

food proteins that changes in functional behavior can be achieved.

1.1 Food Proteins

Food proteins are derived from a number of sources: plants, meat and fish, milk, eggs, and microbial proteins from unicellular or multicellular organisms, for example, bacteria, yeast, molds, and algae. Plant proteins are broadly classified according to their solubility, shape, prosthetic group, regulatory properties, as well as biological activity. They were first classified on the basis of their solubility as albumins, globulins, glutenins, and prolamines. Albumins are the most water-soluble globular proteins. The next most soluble proteins are globulins such as conglycinin (7S) and glycinin (11S) from soybean, which are soluble in dilute salt solutions at neutral pH. Glutenins such as wheat glutenins are soluble in dilute acid or alkali. Prolamines are corn or wheat storage proteins and are soluble in 70% ethanol.

Muscle or contractile proteins are derived directly from animal tissue and are the most conspicuous food proteins in the human diet. Muscle proteins are generally classified into three groups on the basis of their solubility in water: sarcoplasmic proteins, which are soluble in water or dilute salt; myofibrillar proteins, which are soluble in salt solution >0.6 M; and stromal proteins, which are the least soluble class of muscle proteins. Fibrous proteins, for example, myofibrillar proteins such as actin and myosin, or stromal proteins, such as collagen and elastin, have polypeptide chains arranged in long strands and serve a structural or protective role. Collagen, the major protein of connective tissue, occurs in several polymorphic forms consisting of three intertwined polypeptide chains.

Egg proteins are primarily globular proteins found in the albumen (egg white) and include ovalbumin, conalbumin, ovotransferrin, ovomucoid, and lysozyme. The egg yolk contains a variety of lipoproteins that act as emulsifying agents, as well as livetin (possibly derived from hen's blood) and phosvitin, an iron carrier.

Milk proteins consist of a colloidal dispersion of casein micelles and soluble whey proteins; their stability is of tremendous practical importance in the dairy industry. Caseins constitute nearly 80% of the total milk proteins. Casein micelles serve to fluidize proteins and solubilize the calcium and phosphate. They are extremely sensitive to changes in ionic environment and readily aggregate with increased concentration of calcium and magnesium ion or below the isoelectric point (pI). β-Lactoglobulin, α-lactalbumin, and lactoferrin are the three most abundant whey proteins in milk.

Other food proteins classified according to their prosthetic groups (tightly associated non-amino acid moieties) are lipoproteins, glycoproteins, and myoglobins (including hemoglobin) with attached fat or oil, sugar, or iron groups.

Proteins derived from unicellular organisms are grown on food processing by-products from which the protein is harvested and subsequently purified.

1.2 Enzymes

Enzymes are proteins that function as specific biological catalysts for chemical reactions in living systems. Enzymes are much more efficient and specific than other catalysts and operate in restricted conditions of temperature and pH. They

are frequently used in the food industry to modify the functional behavior of food proteins. For instance, proteases, which hydrolyze peptide bonds, can be recovered from plant sources such as papain and are used as commercial meat tenderizers. It is important, however, that the nutritive value of the product not be significantly reduced by the hydrolysis of the peptide bond of the protein catalyzed by the enzyme.

Enzymatic action on free amino acids is of significance in food spoilage and production of flavors in fermented foods. For example, enzymatic degradation of free amino acids by microorganisms of the genera *Staphylococcus, Pseudomonas,* and *Micrococcus* produces specific enzymes that are responsible for the degradation reactions. Enzymes are also used in the manufacture of beer, bread, cheese, coffee, vinegar, vitamins, and many other products.

1.3 Energy and Nutritive Value

The nutritional quality of proteins is essentially determined by their amino acid composition. The nutritional value of a protein for human consumption is based on the content of essential amino acids compared with human requirements and on the protein efficiency ratio (PER), which is determined by the weight gain of a rat divided by the protein intake. Nutrient availability and quality of food proteins depend on the processing treatments and interaction with other food components. Protein requirements for maintaining good health and growth are listed as the recommended dietary allowance (RDA) set by the US National Academy of Sciences. The RDA for a certain population varies depending on such factors as age, sex, level of activity, and individual metabolic factors. Protein requirements to meet growth and maintenance range from 2.0 g kg^{-1} body weight for infants to 0.8 g kg^{-1} body weight for adults. Energy needs increase during pregnancy, lactation, as well as during work, stress, sickness, and aging. Proteins differ in nutrient value because of differences in amino acid composition. Protein quality is measured by chemical scores and biological assays that assess such qualities as content of essential amino acids, nitrogen value, limiting amino acids, and efficiency ratio. Some sources of animal proteins include cheese, eggs, fish, meat, and milk. Vegetable proteins can be found in beans, grains, nuts, and a variety of vegetables.

2 Protein Interactions

Molecular forces governing protein interactions determine the relationship of the structure of individual proteins to their functional properties as well as the association of a protein with other compounds in the cell. These forces include covalent bonds, ionic interactions, hydrogen bonding, hydrophobic interactions, hydration, and steric repulsion. Covalent bonds include all the bonds of the primary structure of the protein as well as disulfide bonds, which are formed between cysteine residues and are dependent on the conformation and structure of the peptide chain. Of the covalent forces, disulfide bonding is the most important in protein interactions. Ionic interactions are between electrostatic charges and are the most fundamental noncovalent attractions in intermolecular forces. Noncovalent molecular forces are one to three orders of magnitude smaller than covalent bonding energy and include

hydrogen bonds, hydrophobic interaction, and repulsion forces. Protein denaturation involves the interruption of these noncovalent forces and results in changes in the secondary and tertiary structures. Proteolysis by appropriate enzymes or hydrolysis with strong acid or base is necessary to break covalently linked peptide bonds. Association and disassociation of the protein in secondary and tertiary structure maintain the integrity of food proteins.

2.1 Protein–protein

Protein–protein interactions often occur as a result of food processing that is designed to improve the functional properties of proteins for new product application. These interactions occur in two-stage processes consisting of unfolding of the native protein and exposing active sites, followed by association of the polypeptide chain through covalent and noncovalent forces. Figure 3 represents a molecular dynamics–simulated process of protein unfolding. Native bovine α-lactalbumin is a globular protein that undergoes gradual unfolding as a function of temperature. The final unfolded state maintains little secondary and tertiary structures with increased entropy relative to its native state. Stable protein interactions are established through cross-linking, ionic, hydrogen bonding, and hydrophobic interactions. Gelation is an association of proteins existing in a three-dimensional network with trapped water molecules. Protein cross-links are formed through formation of disulfide bonds by sulfhydryl groups or through hydrophobic interactions. To maintain a stable gel, a balance must exist between forces that promote formation of the network and those that oppose the formation.

2.2 Carbohydrates

Proteins and carbohydrates form irreversible complexes in nonoxidation reactions. Food protein heated in the presence of a reducing sugar results in the reaction

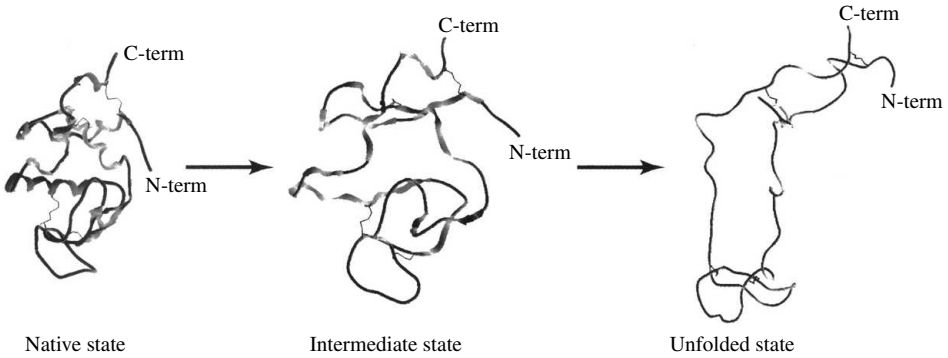

Fig. 3 Molecular dynamics simulation of the two-step unfolding process of bovine apo-α-lactalbumin in vacuum. The native state is taken from the X-ray crystal structure (PDB code 1HFZ) without Ca^{2+}, the intermediate state is a snapshot of a conformation during the simulation, and the unfolded state is achieved by heating the native molecule that reached equilibrium. Four disulfide bonds formed between the cysteine residues greatly stabilize the molecule.

of the carbonyl groups of the carbohydrate with the free amino group of the protein, followed by a cascade of reactions leading to polymers. These Maillard reactions are the major cause of protein damage in the drying of milk at moderate temperatures. In the early stages of the Maillard reaction (Fig. 4), the carbonyl of the reducing sugar undergoes nucleophilic attack by the amine, followed by loss of water and ring closure to form the glycosylamine. The Amadori rearrangement follows with the formation of 1-amino-2-keto sugar, which has been isolated and identified in browned dried fruit. However, more severe heating, required in the preparation of toasted breakfast cereals, bread, and biscuits, results in late Maillard-type damage and the formation of other undesirable by-products. One such by-product is acrylamide, a known animal carcinogen and human neurotoxin. Acrylamide is formed when the amino acid asparagine reacts with simple sugars at high temperature, as in fried or baked foods.

2.3 Lipids

Protein–lipid interactions in nature occur in food systems such as milk and eggs. These interactions occur most notably at the cellular and intracellular membrane level. Proteins that stabilize emulsions can adopt conformations that are capable of interacting with both lipid and aqueous phases by assuming the lowest free-energy form at the interface. The process can be represented in two steps: diffusion-controlled sorption at the interface, followed by protein unfolding. Emulsions are stabilized by hydrophobic interactions between the apolar region of the protein and the apolar aliphatic chain of the lipid. The importance of hydrophobic interactions has been convincingly demonstrated

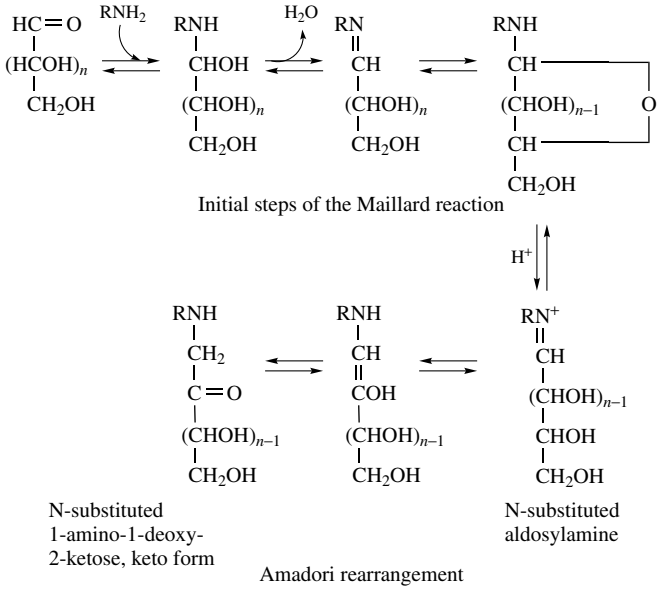

Fig. 4 Schematic representations of the Maillard reactions and the Amadori rearrangement.

in model systems in which the energy of protein–lipid interaction reaches a maximum around the pI of the protein. Protein–lipid interaction can be increased by high-pressure homogenization, which increases the number of lipid droplets and the interfacial surface area. Lipids protect proteins against thermal denaturation because of their high heat capacity and the absence of water. Strong interactions occur in flour–water mixtures, in which lipids can bind gluten proteins to form highly stable lipoglutenin complexes.

2.4 Hydration

Interactions of protein side chains with water determine the intrinsic properties of a protein, such as solubility, swelling, dispersibility, and wettability. Water absorption is considered as the most important step to imparting desired functional properties to proteins. Proteins interact with water through their side chains or backbone, and their solubility depends on factors such as hydrogen bonding, dipole–dipole and ionic interactions, pH, and temperature. Their ability to absorb and retain water plays a major role in the textural stability of food systems. Texturized proteins may be used to formulate meat or seafood analogues by taking advantage of their hydration properties.

2.5 Soluble Ions

Sodium, potassium, and calcium are the most important ionic components associated with solubility of proteins. The reactive nature of proteins allows for the manipulation of the ions to accomplish food preservation by, for example, controlled dehydration. Proteins are stable within a defined range of pH and may have either net positive or negative charges or may be neutral. At pH values above or below their pI, proteins interact more readily with water molecules to improve solubility. Divalent cations also act as the cofactors that are essential for some enzymes to be catalytically active. Salts used in food processing can denature proteins by charge neutralization. Severe denaturation results in irreversible realignment of the native structure of the protein.

3 Functional Protein Interactions

Physicochemical properties that enable proteins to affect the characteristics of foods during processing, storage, preparation, and consumption define the functional properties of proteins. Protein functions that affect food utilization are (1) water absorption – viscosity and gelation; (2) surface activity – gelation and foaming; and (3) chemical reactivity – textural properties. The functionality of a food product is determined experimentally because, while the study of protein structure provides information on physicochemical properties, the exact relationship between structure and function has not been fully understood. Changes in functionality are the result of protein interaction with water, other proteins, or the result of changes in the surface characteristics of the protein molecule.

3.1 Gelation and Rheology

Gelation is the formation of an extended network of denatured protein aggregates held together by intermolecular forces.

Gels can result from controlled protein denaturation and unfolding (egg white); controlled folding and realignment (collagen); controlled unfolding, disulfide interchange, and enhanced hydrophobic interactions (gluten); and enzyme hydrolysis and hydrophobic interactions (rennet milk gels). The stability of gels largely depends on the balance of hydrophobic interactions, hydrogen bonding, and electrostatic forces, which, in turn, are affected by pH and electrolyte content. Cross-linking of proteins in the matrix via disulfide bonds leads to the formation of heat-irreversible gels that are subsequently stabilized by hydrogen bonds. Higher–molecular weight proteins, with a larger percentage of hydrophobic amino acid residues, tend to form stronger gels.

Rheology describes how materials flow and deform during exposure to various force applications. Many factors affect the ability to flow, including concentration, temperature, and microstructure. Dairy-based foods, including chocolate milk, puddings, and processed cheeses, rely on protein–hydrocolloid interactions to impart stability and enhance the texture of the food system.

3.2 Emulsification

A stable protein emulsion is produced when proteins in a two-phase medium, accompanied by energy input (usually a combination of shear and heat), unfold slightly at the interface and align their nonpolar regions toward an oil phase with their hydrophilic regions toward the aqueous phase. The balance of the hydrophilic and hydrophobic forces in the protein maintains emulsion stability. Globular proteins with a highly ordered and stable tertiary structure, such as β-lactoglobulin, bovine serum albumin, and lysozyme are more likely to unfold and are considered to be good emulsifiers. Emulsification activity continues to increase with increasing degree of protein denaturation, provided solubility is not compromised. Surface hydrophobicity of proteins has been directly correlated with emulsifying activity. Emulsions are mechanically unstable and will separate over time. The breakdown in stability results in flocculation followed by coalescence of the particles by forces, as depicted in Fig. 5. Although emulsifiers can minimize interfacial surface energy and reduce

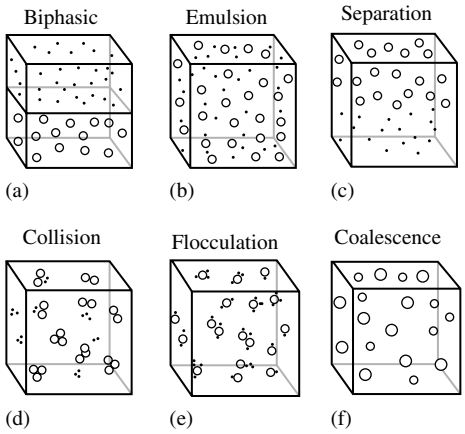

Fig. 5 Process of emulsion formation and breakdown. (a) Biphasic medium of liquid and semisolid emulsion, (b) thermodynamically unstable emulsion, (c) gradual migration of emulsion based on charge separation, (d) particle collision with increasing electrostatic charges, (e) clear aggregation and flocculation of collided particles, and (f) coalescence and syneresis of emulsion.

coalescence, emulsions gradually separate into two phases as the repulsive electrical charges decrease. Gradual increase in free energy leads to more frequent collisions of similarly charged particles. These collisions produce flocculated globules or clusters, which will continue to grow unless conditions change. Complete breakdown of the emulsion is the result of coalescence of these particles.

3.3 Foaming

Protein foams are emulsions of gas in a continuous aqueous protein phase containing various surfactants to prevent coalescence. Foods such as ice cream and whipped toppings are examples of stable foams formed by incorporation of a large volume of air during processing. Air is forced into the medium through mechanical mixing that increases the volume over 1,000%. Foam stability is maintained by surfactants that resist the influence of gravity, pressure, and temperature, which tend to rupture the stable emulsion. Controlled denaturation of the native protein by shear, temperature, or manipulation of electrostatic balance increases hydrophobicity and improves foaming. Foam-stabilizing conditions include high surface hydrophobicity, low net charge, minimal electrostatic repulsion, good solubility, and reasonable protein concentration. Foam expansion (overrun) is controlled by metering the mix and air into the equipment in proper proportions to form air cells of the desired size; overrun is computed as the percentage increase in the volume or the percentage decrease in the density of the mix. Foam stability may be controlled by addition of combinations of stabilizers and emulsifiers, such as salts, sugars, lipids, cations, proteins, and energy input (heat and shear) during processing. As foams age during storage, they shrink, leading to loss of air and separation.

3.4 Thermal Processing

Food proteins are thermally processed to enhance functionality, improve textural properties, or retard deterioration. In the preservation of fruits and vegetables (blanching), heat is used to denature enzymes. Processing may lead to a slight loss in nutritional quality. Most processes, however, improve quality by destroying antinutritional factors through inactivation of enzymes such as trypsin inhibitor or peroxidase. Complete denaturation of peroxidase (EC.1.11.1.7) is used as an indicator of adequate processing. Protein–protein interactions may be enhanced, leading to formation of new complexes. Factors such as temperature, the presence of salts and oxidizing/reducing agents may be used to produce desirable high-quality foods. Chilling or heating can denature proteins. Protein structure may be altered as a result of changes in the electric potential, pH, and so on, and such changes can be used to enhance functionality in food. Thermal denaturation of food proteins generally occurs between 45 and 85 °C, accompanied by exposure of hydrophobic groups that can lead to protein aggregation. More severe treatments can result in the splitting of the disulfide cross-links with release of hydrogen sulfide as well as alteration of amino acid residues with the formation of new intra- or intermolecular covalent cross-links. Low-temperature denaturation is mediated by a reduction of hydrophobic interactions

in conjunction with enhanced hydrogen bonding, leading to aggregation and precipitation of proteins.

3.5 Thermally Induced Mutagens

Mutagens are substances that cause heritable genetic changes (mutations). Most mutations are harmful and most mutagens are carcinogens and vice versa. Heterocyclic aromatic amines (HAAs) that are formed during broiling, grilling, roasting, or frying of meat and fish have been found to have a tumorigenic effect in various organs in mice, rats, and nonhuman primates, and many of them are therefore considered as possible human carcinogens. More than a dozen highly mutagenic HAAs have been identified; the most common forms are amino-imidazo-azaarenes (imidazoquinolines, imidazoquinoxalines, and imidazopyridines) and carbolines (pyridoindoles and pyridoimidazoles). The Millard reaction has been suggested to be a pathway for the formation of the imidazoquinoline or imidazoquinoxaline type of heterocyclic amines. Creatine and creatinine, free amino acids, and sugars have been shown as precursors. The same precursors may form the imidazopyridines. Aminocarbolines may be generated by the pyrolysis of amino acids and proteins. Precursors and tentative reaction routes for their formation have been identified from model experiments. It has been shown that when fried, different sorts of meat form different types and amounts of HAAs. Cooking conditions (temperature) and the amounts of different precursors may influence the formation and level of HAAs in food products. Extensive research has been carried out to develop methods to reduce or eliminate such compounds from the food supply, with moderate success.

4 Food Protein Functionality

Food proteins with special functional properties are manufactured by manipulating changes in the native secondary and tertiary conformations. Intermediate as well as stable forms of conformations may be produced at various stages of processing (Fig. 3). Food products with different functionality are created because of the large range of structures and their interaction with one another. This complex variety of conformations displays different properties such as water sorption, holding, and sorption, which are important functional attributes. The physical ability to entrap and hold water and lipid are essential for foaming. The ability of proteins to denature and form cohesive viscous matrices is what gives rise to their emulsifying and film-forming properties. The structure of the matrix formed depends on the nature of the protein; for instance, plasma protein gels form a ''close'' dense network and egg albumin gels form an ''open'' structure. Although the question of how a protein folds into a unique shape with specific functions is far from being solved, it is generally accepted that the primary amino acid sequence encodes its folding pathway, which in turn determines its functionality.

4.1 Partially Folded Proteins

The concept of the molten globule has been used to describe a partially folded equilibrium state between native and unfolded states. This intermediate has been found for many proteins in mild denaturing conditions, such as low or high pH, high temperature, or moderate concentrations of chemical denaturants (urea and guanidinium hydrochloride). The molten

globule is almost as compact as the native state and has a loosely packed hydrophobic core. It possesses pronounced secondary structure but little rigid tertiary structure and marked loss of enzymatic activity relative to its native state. It has long been established that changing the food protein structure can result in the alteration of food functionality. Thus, our basic understanding of the protein-folding process and the intermediates involved can directly lead to not only fundamental understanding of processing treatment but also the discovery and utilization of valuable food ingredients.

4.2 Properties of the Molten Globule State

The recently emerged energy-landscape theory and funnel concept for protein folding have provided us with a quantitative and pictorial view of the folding process. They revealed that multistep mechanisms that involve heterogeneous populations of molten globule–like intermediates may be more common than we previously realized. Many food proteins have been found to exist as the molten globule states under various conditions. α-Lactalbumin, at acidic pH, elevated temperature, or in the absence of calcium, is a paradigm of the classical molten globule state. Moreover, the number of proteins that has been found to possess structural features of the molten globule state as well as remain biologically functional is increasing drastically.

The typical molten globule state is more open than the native sate, but still represents a compact structure. The dynamic and flexible characteristics of the molten globule state allow water molecules to penetrate the protein more easily. The molten globule state is thus highly hydrated. In addition, the loosely packed side chains may emphasize the importance of solvent-separated hydrophobic interactions in the molten globule state.

In contrast with the association process in native proteins in which multimeric complexes are often formed, protein–protein interaction in the molten globule states may lead to aggregation. Recent research on human α-lactalbumin has suggested that polymeric forms of the protein may serve as antitumor and antibacterial agents.

4.3 Functional Applications

The knowledge that a single whey protein such as α-lactalbumin may have a myriad stable intermediate stages has become the basis for many new functional food ingredients derived from whey. Processing technologies have the potential to create many products from native, partially folded, or completely unfolded proteins.

Food proteins such as whey proteins can be modified using chemicals, heat, or shear in extrusion processes. Chemical treatment alone alters the reactive groups of the amino acids, resulting in not only selected changes in covalent bonding but also in the noncovalent forces that influence conformation such as van der Waals forces, electrostatic interactions, hydrophobic interactions, and hydrogen bonding. Heat and shear, on the other hand, alter the conformational structure of the protein through some degree of denaturation of the protein, exposing hydrophobic groups that are normally buried in the interior of the native protein. The changes caused by denaturation can be either reversible or irreversible. As the whey proteins denature, they become insoluble and show a great tendency to

aggregate. Heat-denatured whey proteins produce different fractions depending on the pH; for instance, whey proteins heated at 90 °C for 30 min at pH 2.5 remain soluble in aqueous solution but exhibit partial loss of solubility when the pH is raised to 4.5. There are two fractions at pH 4.5, one is the partially and irreversibly unfolded proteins (mainly α-lactalbumin and β-lactoglobulin) and the other is the nondenatured proteins, similar to the native proteins. An application of this temperature- and pH-dependent solubility behavior of whey proteins is whey gels at pH 7 after being heated for 120 min, exhibiting very low elasticity, firmness, and low solubility, an attribute that has been used in manufacturing soft, drinkable dairy products such as yogurts.

Fine-stranded particulate aggregates of heat-denatured whey proteins as visualized by atomic-force microscopy reveal a network structure in a heat-induced globular gel that is strongly dependent on the balance between attractive and repulsive forces among denatured protein molecules during aggregation. If the pH is far from the isoelectric point, and the ionic strength is sufficiently low, intermolecular electrostatic repulsion is dominant. Structural transitions are visible at the macroscopic level: fine-stranded gels are translucent, while particulate gels are opaque and syneresic. A fine-stranded gel formed at neutral pH is rubbery and deformable and can form a large strain without fracturing. The same gel, at acidic pH, however, is brittle because intramolecular disulfide bonding is unlikely to occur. Heat-induced aggregation of β-lactoglobulin follows a two-step model at neutral pH, in which small particles are formed first followed by aggregation into large clusters.

Twin-screw extrusion processing has been used by the food industries to impart unique properties and functionality to food proteins. The shear developed in extrusion processing, which can be controlled by varying the screw speed, is used to vary the degree of denaturation. By controlling the operating conditions, such as the amount of operating shear and the level of moisture, a variety of partially denatured products can be created with modified biological and nutritional functions. Furthermore, the combination of heat and shear in the extruder can accelerate the directed conformational changes considerably. If changes in globular-structured proteins occur at 80 °C with heat treatment alone, for example, significant denaturation or even unfolding can occur at 75 °C with the addition of shear in the extruder. At high shear and pH 8.0, whey proteins are texturized to form stringy products that are useful as meat extenders.

Keywords

Footprinting
A technique used for probing macromolecular structures and interactions. It relies on the fact that some regions of the macromolecule are buried or become inaccessible as a consequence of their structures/interactions. Enzymes or chemical reagents are used as probes of the structure.

DNase I
An endonuclease (cleaves internally) for digestion of DNA. Has modest sequence specificity but generally cleaves at most sites in DNA.

Hydroxyl Radical
Highly reactive and unstable molecular species. Its small size and nondiscriminating high reactivity makes it an ideal probe for footprinting.

One-hit Kinetics
A characteristic of cleavage-based footprinting techniques that achieve limited cleavage of the population of macromolecules, such that, on average, each molecule cleaved is cleaved only once.

Fenton Chemistry
The most commonly used chemical method to generate hydroxyl radicals. The reaction is based on homolysis of hydrogen peroxide catalyzed by Fe(II) ion. By the reaction, Fe(II) ion is oxidized to Fe(III) ion and regenerated by the reductant (thiols, ascorbate) in the reagent.

Radiolysis
Chemical reaction driven by direct absorption of ionizing radiation energy. Particularly, aqueous solutions in the biological system generate the hydroxyl radicals through the absorption of ionizing radiation.

Reverse Transcriptase
The enzyme that makes the complementary DNA chain from RNA (reverse transcription). (Note: DNA polymerase makes DNA copy from DNA.)

Primer Extension
A technique commonly used for detecting chemical modification or cleavage of nucleic acids. Synthesized oligonucleotides are hybridized to specific sequence on the target nucleic acid and extended by the enzyme (DNA polymerase or reverse transcriptase). The enzyme stops at the modification or scission sites, and in electrophoretic separation, they appear as missing bands.

In Vivo Footprinting
Footprinting technique directly applied to living cells. It has a capability of probing interaction/structure *in situ* in a biological system.

Footprinting technology includes *in vitro* and *in vivo* methods of examining the average structure of macromolecules on the basis of the solvent accessibility and sensitivity of the macromolecule to covalent modification or cleavage. Analytical methods to separate, identify, and quantitate the unmodified and modified macromolecules are essential features of the method. In addition, a key characteristic of all footprinting assays is that the modification or cleavage reaction is of limited extent, such that the information obtained from the population of macromolecules represents the structure of the intact molecule, and thus is biologically relevant. For footprinting of nucleic acids, cleavage of accessible sites on the backbone or covalent modification of accessible bases is carried out in order to probe the structure. For cleavage-based methods, cleavage of the backbone is limited, such that on average, each molecule cleaved is cleaved only once. Sequencing gels are used to analyze the cleaved products; this allows structure probing at the monomer level due to the high resolution of the gels.

1 Principles

1.1 Background and History of Nucleic Acid Footprinting

Proteins that bind to specific regions of DNA play critical roles in the expression of genes and in the replication of the genome. Nucleic acid footprinting approaches were developed to understand specific interactions between DNA and proteins, and these investigations were quite active in the early to mid-1970s. The initial approaches in examining the specific interactions of protein and nucleic acids were of two types: the first involved isolation and characterization of a fragment of DNA that was bound to a protein of interest. The protected fragment isolation procedure involved digestion of DNA in the presence of the binding protein under study using DNase, and then subsequent chromatographic isolation of the remaining intact DNA followed by radioactive labeling and sequencing. At the time the protected fragment isolation methods were in use, Mirzabekov and coworkers and later Ptashne and coworkers recognized the value of methylation protection as a method to map protein–DNA interactions. In this case, the footprinting reagent dimethylsulfate (DMS) reacts with the N-7 of guanines and the N-3 of adenines to produce piperidine-labile sites. Specific protein contacts with these sites can block reactivity, resulting in reduced cleavage and thus identify the specific sequences involved in the binding.

Both these procedures fit the definition of ''footprinting'' as outlined for the purposes of this article, and they illustrate

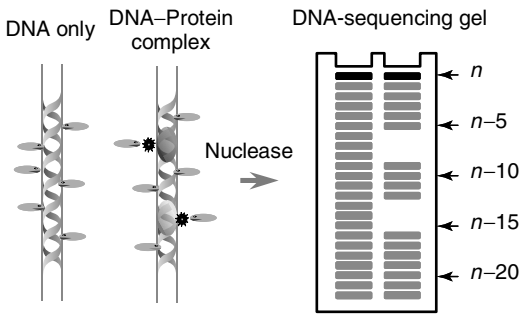

Fig. 1 Schematic representation of footprinting experiment. The nucleic acid reacts with the specific probe used to probe the macromolecule. The left-hand panel shows that all nucleotides are attacked equally, thus producing the uniform pattern in electrophoresis (right panel, left lane). If the nucleic acid interacts with proteins, the protein covers particular regions of the nucleic acid and prevents the attack by probe (middle panel), which results in missing bands in electrophoresis (right panel, right lane).

the two distinct approaches that are commonly used: that of cleavage versus modification of the nucleic acid to be probed. However, the term footprinting only came into common usage after the publication of the seminal articles by David Galas and Albert Schmitz. Since 1978, over 5000 publications using the term ''footprinting'' have been deposited in the PubMed database of the National Library of Medicine. (There are several references to footprinting in PubMed that precede 1978; these refer to ''footprinting'' of infants as a means of identification.)

The general experiment is outlined in Fig. 1. A DNA fragment is end labeled, typically with ^{32}P, although other labeling schemes can be used. Two conditions are illustrated, one in which the DNA binding protein is absent, the second in which two different proteins are added that bind to the DNA at discrete sites. The two samples are exposed to a limited dose of nuclease that, in the case illustrated, can cleave at each base position on the DNA with an equal probability. (Note that in the case of modification, the concept is similar, except that modification occurs only at the susceptible sites, cleavage is generated in a subsequent chemical work-up). In the case of the specific DNA binding sites, the nuclease is blocked from cleaving the DNA. The labeled fragments are isolated and run on a sequencing gel, separating the individual fragments. Since each position is cleaved with equal probability, one can, in the left-hand lane, see a complete set of fragments that represent DNA molecules of individual lengths ranging from the length of the uncleaved DNA, seen as the dark band at the top (length *n*), to fragments of length *n*-22, which appears at the bottom of the gel, with all the individual fragments in between. In the right-hand lane, the pattern is different – the bands from *n*-6 to *n*-8 and those from *n*-13 to *n*-15 are reduced in intensity. The limited dose provides a wide distribution of fragments. The binding of the protein reduces the reactivity of the nuclease at a number of distinct sites relative to the reactivity of those sites in the absence of protein. The data provides a map of the specific sites within the DNA in which the protein is indicated to bind.

Although these approaches using DNase I and DMS have been invaluable, additional footprinting assays have been developed using a wide range of enzymatic and chemical nucleases. In particular, some of the drawbacks of a number of chemical and enzymatic footprinting reagents include preference of a footprinting reagent for specific positions along the DNA and limiting the number of sites that can be

probed. For example, nucleases tend to cut only at a subset of the positions along the DNA backbone. Modification reagents like DMS result in cleavage at adenine- and guanine-containing sites that are accessible and thus susceptible to methylation; they cannot probe at cytosine or thymine. In addition, DNase I, since it is often of the same size as the protein that is bound to DNA, has a further disadvantage in that it can overestimate the size of the protected region, as well as be blind to any variations in reactivity within the binding site. Chemical nucleases, if they are small, can provide enhanced structural information compared to enzymatic nucleases. The most effective of these reagents and the one in widespread use is the hydroxyl radical (•OH), which is commonly generated by the venerable Fenton–Haber–Weiss reaction using Fe(II)-EDTA as a catalyst, which was developed by Tullius and coworkers. The •OH radical cleaves DNA by abstracting a hydrogen atom from the ribose/deoxyribose sugars along the DNA backbone; thus, there is virtually no sequence dependence and each position can be cleaved with equal probability. The size of the •OH radical is also advantageous; it has a Van der Walls surface area similar to that of water and thus its ability to react is highly correlated to the solvent accessibility of the reactive positions with the nucleic acid.

At the same time that new reagents were being developed for conducting footprinting experiments, protocols were developed for conducting quantitative equilibrium and kinetic footprinting experiments, initially using DNase I as the footprinting probe, but later incorporating hydroxyl radical–based methods because of their enhanced structural resolution. The development of quantitative footprinting required the development of statistical thermodynamic approaches to analyze multiple-site binding data and their interactions, and was aided by the advent of digital imaging technologies (PhosphorImagers) for the detection and quantitative analysis of radioactively labeled gels. Although the general approaches to analysis of individual sites, even at the single-nucleotide resolution, were prophesied by Galas & Schmitz, the use of explicit thermodynamics models in data analysis and imaging technologies in the digitization of data were significant advances.

Thus, experiments like those illustrated in Fig. 1 were transformed into multiple lanes where the protein concentration was titrated across a wide range of concentrations, the specific density within a binding site was quantitated from the digitized image, and the density changes as a function of protein concentration were analyzed in detail. This allowed the thermodynamic affinity of, and cooperativity among, individual sites involved in the DNA–protein interaction to be determined. The successes with DNase I equilibrium methods stimulated progress in the use of the •OH radical, with its enhanced structural resolution, in the probing of individual site binding isotherms. In addition, new scientific problems involving the structural rearrangements of catalytic RNA arose, and Cech and coworkers applied high-resolution •OH radical footprinting to the study of RNA structure and function allowing the monitoring of individual sites within the RNA as a function of ligand binding. This opened up a number of exciting opportunities for research in the RNA field and posed a challenge to footprinting technologies in that, for the nearly 400-nucleotide *Tetrahymena* ribozyme, structural information was, in principle, available at each and every nucleotide within the RNA. It was not until over 10 years

later that this potential structural resolution was harnessed, when single-band analysis of the folding of the L-21 RNA over its entire length was demonstrated.

Subsequent to the success in the analysis of equilibrium transitions, the method of DNase I footprinting was extended to kinetic analysis in the hundreds of millisecond range. In these experiments, protein and DNA were mixed in a stopped-flow device and given a pulse of nuclease to probe the location and extent of the macromolecular interaction as a function of time. This, for the first time, allowed individual site kinetic progress curves in the formation of specific DNA–protein contacts to be examined. Although kinetic studies using DNase I were developed by simply increasing the amount of DNase I used in the digestion and thus lowering the time required for sufficient cleavage, a similar approach to Fenton chemistry was not successful, increasing the concentration of reagents did not appreciably reduce the required exposure time to less than the minutes timescale. However, alternative approaches to generating •OH radicals as a probe for time-dependent studies were explored by Anderson and coworkers using peroxonitrous acid to generate •OH. The half-life of the disproportionation of peroxonitrite at neutral pH limited the timescale accessible using this reagent to a few seconds. Other methods of generating •OH radicals include radiolytic sources; however, the typical low-flux sources require exposure times on the order of hours. A breakthrough in the development of the •OH radical as a time-resolved probe of the nucleic acid structure was the application of synchrotron radiation as a radiolysis source; this has allowed time-resolved footprinting down to the tens of millisecond timescales and have been successful in the detailed examination of RNA folding and DNA–protein interactions.

As *in vitro* methods have progressed, *in vivo* footprinting has also had an impact, although the technological development has been slower. In this case, the method requires that the footprinting reagent enter the cell and react at accessible sites. Subsequently, a readout must be generated. This method was originally demonstrated to be successful by Schultz and coworkers on the basis of the genomic sequencing method by Church and Gilbert. Recently, the demonstration by Tullius and Ottinger that radiolysis could provide an effective *in vivo* footprinting tool may make the method more generally applicable.

Figure 2 lists the continuous evolution and remarkable progress of footprinting over the last 30 years; the methods of the prefootprinting era were originally codified and enhanced by Galas & Schmitz in 1978. Since that time, the introduction of high structural resolution footprinting probes, the introduction of quantitative equilibrium methods, the development of *in vivo* methods, and the development of fast time-resolved methods has resulted in footprinting becoming an extremely versatile tool in the understanding of nucleic acid structure and function.

1.2 Fundamental Features of Method

The original publication in *Nucleic Acids Research* was entitled ''DNase footprinting: a simple method for the detection of protein–DNA binding specificity'' and aside from introducing the term, it carefully laid out many of the basic principles of the method that are common to all successful footprinting approaches today. First was the principle of limited cleavage. The authors examined cleavage of labeled

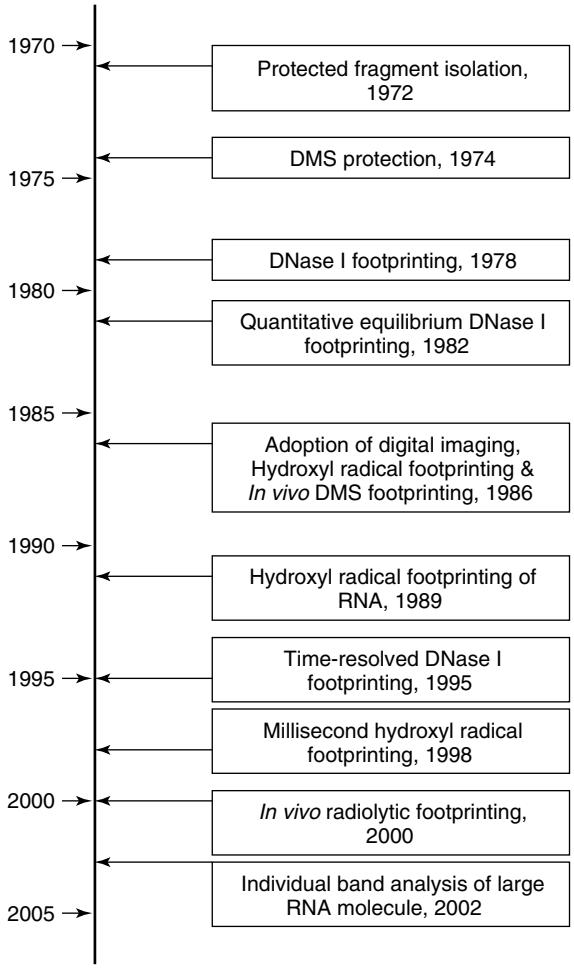

Fig. 2 Time table of development of footprinting techniques.

DNA fragments as a function of incubation time with DNase I, and upon examining the fragment distribution, determined that a limited incubation time was optimal. If the incubation time was too short, there was insufficient cleaved material to detect the products. If the incubation was carried out for an extended time, the population of smaller fragments was emphasized, skewing the distribution and depleting the number of larger fragments. This ''one-hit'' kinetic regime was ''the condition in which those fragments produced have a high probability of coming from a single cut of the original piece of DNA.'' This assured a broad distribution of the fragments. It also provides for the probing of an intact, biochemically relevant population of molecules, as will be shown in this article. The second principle was that of quantitative analysis of the differential reactivity of the distinct sites within the DNA, ultimately suggesting the value of probing each and every site. It was presumed that chemical reaction kinetics would govern the production of cleaved fragments, and

that the differences in the extent of reaction of the nuclease with a number of specific sites as a function of added protein should be measured quantitatively. The ability to accurately measure the individual sites was critical to the analysis. Thus, this paper established the two principles of *limited dose* and *differential reactivity of individual sites* that are fundamental to all footprinting experiments today.

2 Techniques

2.1 DNase Footprinting

DNase I footprinting is one of the oldest techniques invented for nucleic acid structural analysis. The principle is simple. DNase cleaves DNA and generates fragments. Upon protein binding, parts of the DNA are covered by protein not accessible to enzyme and these regions cannot be cleaved. By electrophoretic separation, the end-labeled fragments can be independently examined. The inaccessible regions are visualized as missing bands in the gel as shown in Fig. 1. The technique also depends on the specificity of the enzyme used. DNase I does not have a particularly strong sequence specificity so that many sites within the DNA are probed.

The technique was first invented by Gilbert, Maniatis, and Ptashne as protected fragment isolation. The usefulness of this method was soon realized and it became a mainstream technique for examining DNA/protein interactions. The method was well codified by Galas and Schmitz and was subsequently applied to DNA/protein binding and induced loop formation and later to DNA/drug interactions. The various RNases have also been used for RNA/Protein or RNA folding analysis. The appearance of other footprinting methods (chemical modification, hydroxyl radical) has reduced its use but it is still a viable and important technique.

2.2 Chemical Modification Method

Chemical modification reagents are invaluable probes for the footprinting of both DNA and RNA. In this section, only the reactions that can be achieved under native conditions (e.g. the conditions where DNA/RNA retains its native structure) will be discussed. The reactions can be categorized in two types. The first category is backbone cleavable reactions (diethylpyrocarbonate (DEPC) for Adenine, dimethylsulfate (DMS) for Guanine) and the second category is primer extension that is used for detection of modifications (1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide metho-*p*-toluene sulfonate (CMCT) and kethoxal [β-ethoxy-α-ketobutyraldehyde] for guanine and DMS for cytosine). Although the methylation by DMS occurs on adenine also, there is no established method to remove the methylated base; thus, it is placed in the first category. The methylation at N-7 on guanine does not stop the primer extension reaction; thus, this modification can only be detected by subsequent chemical cleavage. The methylated guanine and cytosine are unstable and subsequently their removal by piperidine for guanine and hydrazine for cytosine results in backbone scission. Similar results can be achieved with other acylation or alkylation reagents such as DEPC (piperidine treatment for scission). Hydroxylamine (cytosine), $KMnO_2$, and OsO_4 (thymine) treatments are likely to produce the pyrimidine glycols whose products are cleavable

by piperidine treatment. The chemistries and reaction products are summarized in Fig. 3.

Compared to backbone footprinting (nucleases and hydroxyl radical), the chemical modification methods require an additional step – either chemical cleavage or primer extension – to detect the products. This inconvenience is compensated by the fact that base-pair configuration can

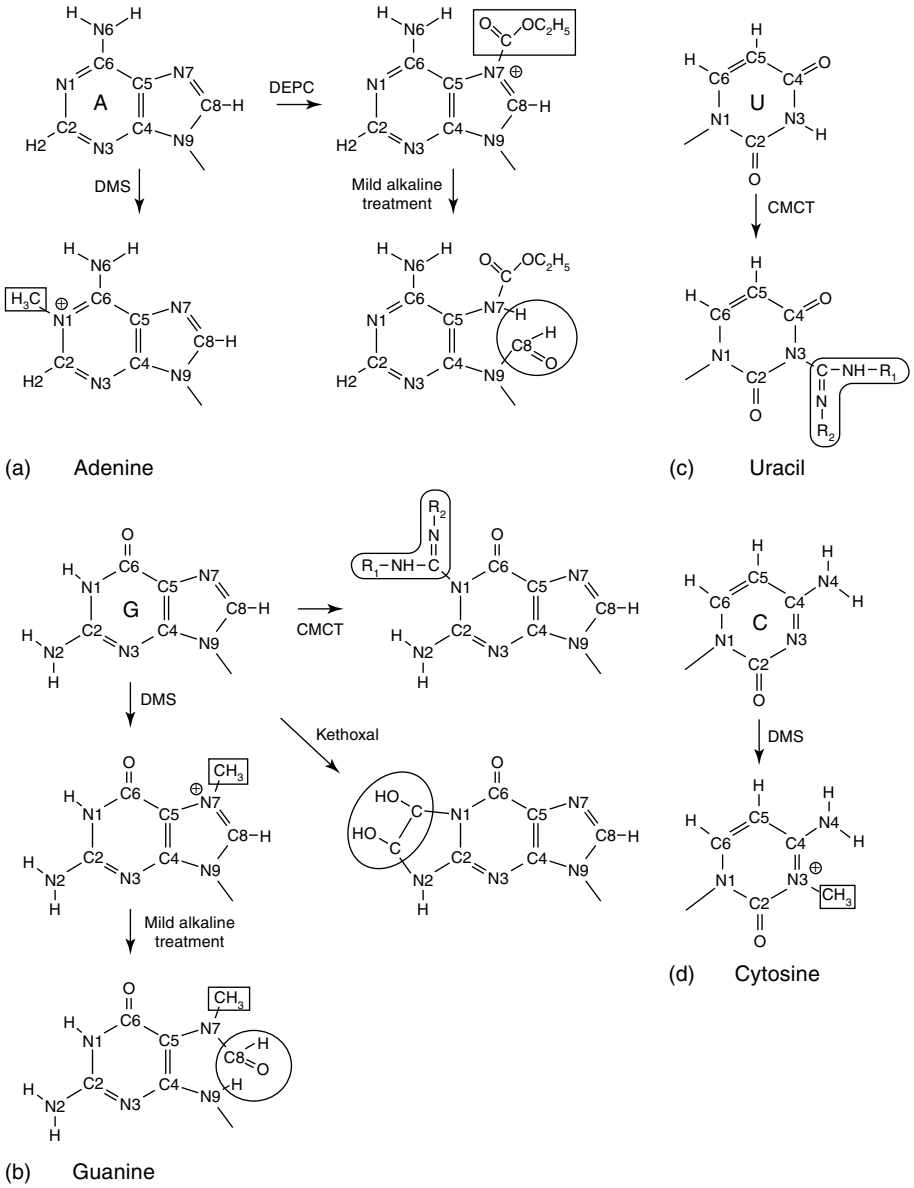

Fig. 3 The chemical modification reactions and reaction products.

be detected in many cases as shown in Fig. 4. The reagent DEPC modifies adenine N-7 that is accessible in the case of Watson–Crick base pair; however, if it is involved in the A-U (reverse) Hoogsteen base pair, it is protected from modification. In this latter base-pair configuration, N1 of adenine is accessible and thus modified by DMS. In the case of the Watson–Crick base pair, it is involved in hydrogen bonding and protected. These features are especially useful for the analysis of RNA structure that often involves noncanonical base pairs. Table 1 summarizes the chemical modifications used for DNA/RNA footprinting.

DEPC was first reported to be reactive with adenine (free and in nucleoside) in 1971, and was mentioned as a potential probe for the nucleic acid structure. Mirzabekov et al. first reported that DMS modifies DNA and later Maxam and Gilbert developed it as a chemical modification probe as well, using it in their famous chemical sequencing method. Peattie and Gilbert introduced DMS and DEPC for RNA tertiary structural analysis of tRNA. They also explored the possibility of using chemical probes for detecting RNA–protein interactions. In 1978, OsO_4 that is specific to thymine was introduced as a chemical modification reagent as an alternative to the Maxam–Gilbert chemistry. The reaction product is likely to be a thymine glycol and can be cleaved by piperidine treatment. $KMnO_4$ and hydroxylamine modifications were developed to replace some of the Maxam–Gilbert chemistries and later used as chemical probes. *N*-ethyl-*N*-nitrosourea was found to be an ethylating reagent for phosphate. It was soon realized that this reagent could be used for binding interference experiments. The modified phosphate prohibits protein binding and nitrocellulose separation of bound and unbound DNA was successfully used for determining promoter–RNA polymerase interactions. The contact site of initiator protein to the promoter region on DNA was determined by DMS. These probes (DEPC, DMS, hydroxylamine, OsO4) have been extensively used to probe DNA and RNA conformations.

The real power of chemical modification was demonstrated by combining the method with primer extension. Primer extension is a technique for detecting the modified bases and backbone scission using DNA polymerase (for DNA) or reverse transcriptase (for RNA). The specific primers for the regions of interest are chemically synthesized. The primers are annealed to the specific site in the sequence and extended by the enzyme. The enzyme stops its extension at the point at which a base is modified or the backbone is cleaved depending on the specific modifications and specificity of the enzyme. The extension reaction is generally carried out with ^{32}P-labeling allowing sensitive detection. The regions of the nucleic acid protected by protein or tertiary contacts within the molecule are neither modified nor cleaved by the reagents; thus, the extension reaction does not stop at those bases and missing bands appear in the electrophoresis results as shown in Fig. 1. Noller and coworkers used CMCT, DMS, and kethoxal as chemical probes and exploited the termination of extension at the modified base in combination with reverse transcription in order to probe the structure of the ribosome. The spectacular work of building the three-dimensional model of the 16S ribosome was done in Noller's laboratory by extensive chemical modification of protein protections on the rRNA in conjunction with the other methods. More

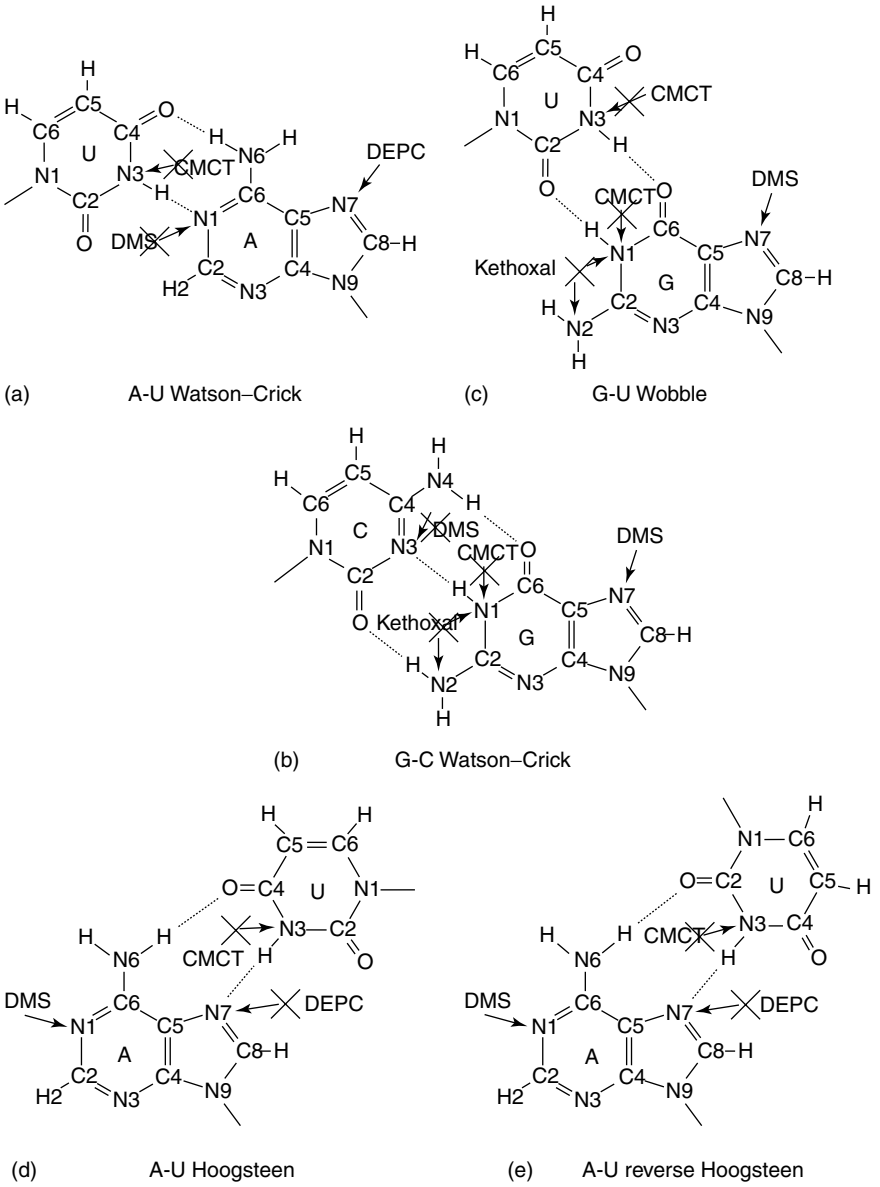

Fig. 4 The effect of base pairs on chemical modifications. The accessibility of modification sites depends on the environment surrounding the nucleotides. The formation of base pairs generally prohibits the chemical modification; however, it also depends on the base-pair configuration. Adenine N7 is open for DEPC in the Watson–Crick base pair, but is involved in a base pair in the Hoogsteen base pair, and thus protected. Adenine N1 has the opposite behavior; it is protected in the Watson–Crick base pair, but is accessible in the case of the Hoogsteen base pair. The careful analysis of chemical modification with multiple probes provides base configuration information in addition to secondary structure information.

Tab. 1 Summary of chemical modification.

Reagent	*Modification site*	**Chemical cleavage*	*Primer extension*	*Note*
CMCT	N1 of guanine	No	Yes	
	N3 of Uracil	No	Yes	
DEPC	N7 of adenine	Yes P	Yes	Detects Hoogsteen base pair
DMS	N1 of adenine	No	Yes	
	N3 of cytosine	Yes H	Yes	
	N7 of guanine	Yes P	No	No W-C detection
Hydroxylamine	C5 & C6 of cytosine	Yes P	–	Products: cytidine glycol (?)
Kethoxal	N1 & N2 of guanine	No	Yes	
$KMnO_4$	C5 & C6 of thymine	Yes P	Yes	Products: thymine glycol
OsO_4	C5 & C6 of thymine	Yes P	Yes	Products: Thymine glycol
Ethylnitrosourea	Backbone phosphate	Yes alkaline	–	Denaturing condition (50% EtOH)

*P stands for piperidine treatment, H stands for hydrazine treatment.

recently, chemical modification was used to prove the existence of alternative secondary structure in the group I ribozyme catalytic core.

2.3 Cleavage Using Hydroxyl Radicals

The hydroxyl radical is one of the most versatile and powerful probes for footprinting. It causes the scission of the polynucleotide backbone by hydrogen abstraction and subsequent strand cleavage. The hydroxyl radical's small size and high reactivity makes it possible to probe the solvent accessibility of the nucleic acid. The cleavage reaction is nonspecific (independent of base sequence) and reactivity strictly depends on the surface accessibility of the target atoms (ribose/deoxyribose 4′ and 5′-carbon).

Hydroxyl radicals can be generated by several methods. The most commonly used method is Fe(II)-EDTA Fenton chemistry. This method has the advantage that the necessary chemicals are easy to obtain, safe to handle, and cheap. A disadvantage is that the cleavage reaction requires exposure times on the order of minutes so that it is not suitable for most kinetic experiments. Peroxonitrous acid can also be used to generate hydroxyl radicals for kinetic analysis. The chemistry involves the homolytic cleavage of the molecule at neutral pH. The method gives a relatively fast burst of the hydroxyl radicals lasting 1 to 2 s. A third method for generating hydroxyl radicals is the radiolysis of water by ionizing radiation such as γ-rays or X-rays. One of the major advantages is that this method does not require added chemicals in order to generate the hydroxyl radicals so that the sample can be in solution conditions optimum for biological interactions. Also, since the source of hydroxyl radicals is water, there is no limit on the amount of hydroxyl radical generation. In the case of the γ-rays, extended time is necessary and hydrogen peroxide accumulation could be a potential problem. Conventional

X-ray sources for crystallography can be used for the hydroxyl radical generation. Hundreds of milliseconds of exposure is sufficient for the footprinting. The most powerful source for the hydroxyl radical generation so far has been high-flux X-ray synchrotron radiation. X-rays generated by a synchrotron light source can carry out footprinting on a millisecond timescale. Some of the chemistries involved in the generation of hydroxyl radicals are summarized in Fig. 5. The advantages and disadvantages of each method are summarized in Table 2.

The reactions involved in backbone scission are summarized in Fig. 6. Hydroxyl radicals abstract hydrogen from accessible and susceptible carbon atoms generating sugar radicals. 4′ and 5′ radicals generally lead to cleavage products; this has been elucidated by the reactivity changes induced by deuteration at each sugar carbon. The reaction paths are different under anaerobic versus aerobic conditions. In this section, we focus on the aerobic reaction. The yield of glycolic acid (4′-carbon attack product) and dialdehyde (5′-carbon attack product) are close to equal under aerobic conditions. Hydroxyl radical footprinting is especially suitable for nucleic acid structural analysis since the sugar-phosphate backbone faces the solvent. The accessibility of the backbone changes dramatically upon protein binding or formation of other tertiary contacts as shown in Fig. 7(a) that shows the loss of band intensity as the result of the formation of a DNA–protein complex as a function of added protein. Tertiary contact formation can also change backbone solvent accessibility significantly depending on the structure formed. Figure 7(b) shows the appearance of protections at specific regions in the Mg^{2+}-dependent folding of the *Tetrahymena* group I ribozyme.

Hydroxyl radical DNA footprinting was introduced by Van Dyke et al. using MPE-Fe(II) (Methidiumpropyl-EDTA-iron(II))

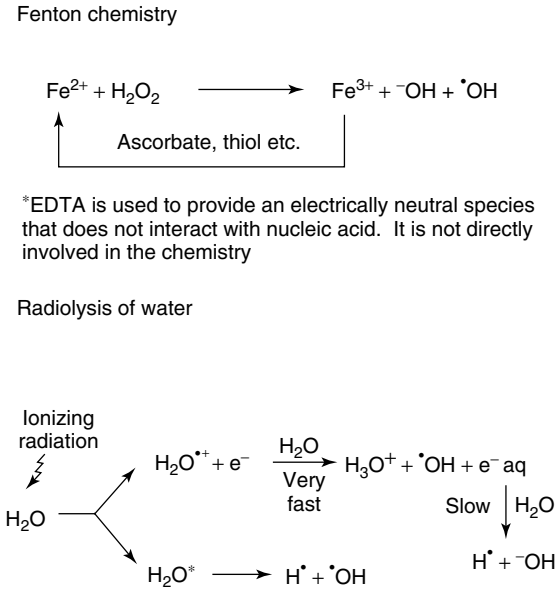

Fig. 5 Generation of hydroxyl radical. The generation of hydroxyl radicals can be achieved by several different ways. The upper panel summarizes the frequently used Fenton chemistry. The hydrogen peroxide undergoes homolysis and generates hydroxyl radical catalyzed by Fe(II) ion that is oxidized to Fe(III). In order to supply hydroxyl radicals continuously, the oxidized Fe(III) ions are reduced by added reductant. The EDTA is not directly involved in the chemistry. It is used for preventing the nonspecific or specific cation binding to the nucleic acid by chelating Fe(II) ions.

Tab. 2 Advantages and disadvantages of methods used for the hydroxyl radical generation.

Method	*Advantage*	*Disadvantage*	*Timescale*
Fenton chemistry	Easy to obtain chemicals, safe to handle, cheap	The scission takes a minute. Not fast enough for kinetics	Minute
Peroxonitrous acid	Fast enough for certain kinetic studies, no special equipment necessary	Reagent is not commercially available	Seconds
Synchrotron X-ray radiolysis	Fastest timescale	Synchrotron beamline is necessary, limited access	Milliseconds

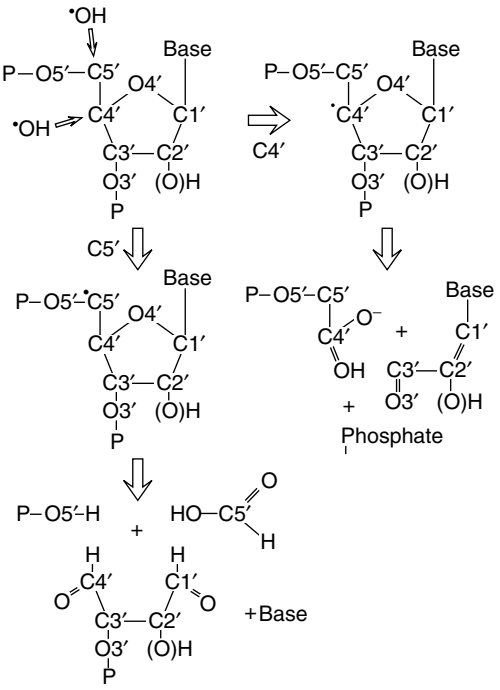

Fig. 6 Summary of backbone scission of nucleic acid by hydroxyl radicals under aerobic conditions. There are several pathways possible for backbone scission reactions induced by hydroxyl radicals. Hydroxyl radical abstracts hydrogens from the sugar carbons, specifically C4′ and C5′ position and producing sugar radicals. The subsequent reactions under aerobic condition lead to the backbone cleavage. The C4′ and C5′ reaction products are produced in almost equal amounts and governed by solvent accessibility of these atoms.

in 1982. This probe specifically intercalates into the double-helical region of DNA and preferentially cleaves the nearby backbones. Superoxide dismutase and catalase that scavenge superoxide were found to inhibit the reaction; the obvious involvement of hydroxyl radicals in the cleavage was pointed out. The versatile Fe(II)-EDTA approach was originally developed by Tullius and Dombroski as a DNA scission reagent and was soon used as a footprinting probe. The above-mentioned features of the hydroxyl radical in conjunction with the high-resolution gel electrophoretic separation of fragments enable the precise mapping of protein binding sites on DNA. Within a few years, it became a popular method for analyzing

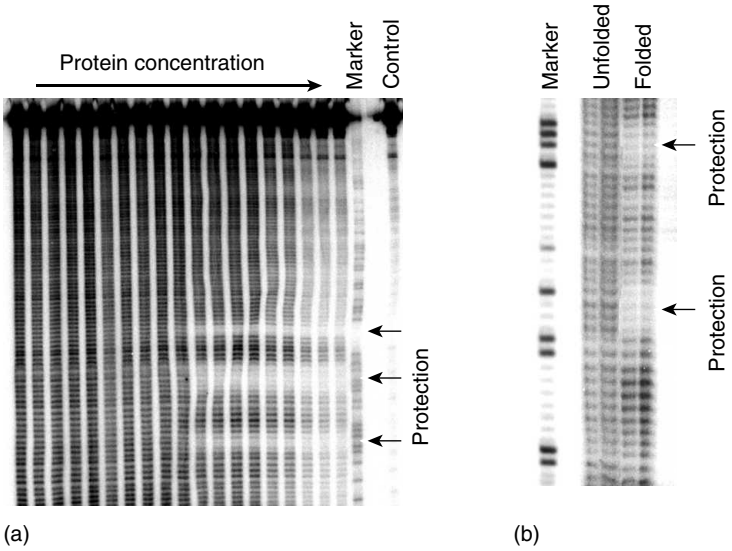

Fig. 7 Example of hydroxyl radical footprinting gel images. Panel (a): a protein titration binding assay. As protein concentration increases, the clear protections appear. Using quantitative analysis, thermodynamic (or kinetic, for progress curve) parameters can be calculated. Panel (b): RNA folding. RNA folds and discrete tertiary contacts form. The contacts may cover the backbone regions of RNA in the molecule and protect the molecule from hydroxyl radical attacks. The image shows modest protection of specific regions due to Mg^{2+}-dependent folding of the *Tetrahymena* group I ribozyme.

protein/DNA interactions. It was originally applied to RNA in the analysis of the pre-mRNA splicing complexes. The method was also applied to a wide range of protein/DNA complexes including nucleoprotein complexes at the replication origin, DNA/drug interactions, branched DNA structures, tRNA structure, and the folding of large RNAs. The method was then reinvented for the kinetic study of DNA–protein binding. The use of the synchrotron approach permits millisecond hydroxyl radical footprinting. The kinetics of *Tetrahymena* group I ribozyme folding were analyzed; the hierarchy of the folding pathway and the acceleration of folding by monovalent cations were revealed by this method.

The short half-life of the hydroxyl radical was exploited as a proximity probe by tethering Fe(II)-EDTA to the ribosomal protein S4. The Fe(II)-EDTA tethered to protein cleaves nucleotides up to 10 Å from the Fe(II) ion, allowing determination of the S4 binding site on the 16S ribosomal RNA. Tethered Fe(II)-EDTA was extensively used in conjunction with primer extension by Noller and coworkers for analysis of the ribosome structure. Recently, tethered Fe(II)-EDTA was utilized for the determination of spatial constraints of RNase P protein cofactor binding site and using these constraints, a model of the holoenzyme was built.

Other probes are available for backbone cleavage. 1,10-phenanthroline-copper

complex was introduced as a chemical nuclease in 1979. The chemistry is likely to be involved in copper-bound hydroxyl radical generation similar to Fenton chemistry. The uranyl(VI) ion (UO_2^{2+}) causes the backbone scission when it is excited by light. The method was applied to tRNA structural analysis and it was suggested that the metal binding site could be detected by this reagent. The iron(II) ion can also be used for probing divalent cation binding sites if it is used without EDTA chelator. Pb(II) can also cleave the backbone with lower specificity. There are also reports on the photochemical cleavage reagents based on acridine and photochemical homolytic cleavage of peroxides.

2.4 Quantitative Equilibrium and Time-resolved Footprinting

The detailed analysis of footprinting data can reveal structural changes in the molecule with single-nucleotide resolution. Since the degree of backbone scission by hydroxyl radicals reports the solvent accessibility of backbone and is independent of base sequence, it is possible to examine how the interaction forms quantitatively without worrying about reaction specificity or steric hindrance. For nucleic acid footprinting techniques, generally an end-labeled sample is used to visualize the reaction products by electrophoretic separation. After electrophoresis, the gel is dried and exposed to a PhosphorImager plate, then scanned (Fig. 8, Panel (a)). The intensity of each band in the digitized image represents the amount of fragment generated. The densitometric analysis of the bands transforms the bands in the gel image to a quantitative representation of the fragments (Fig. 8, Panel (b)). The change in the total density can be plotted and fitted using nonlinear regression algorithms (Fig. 8, Panel (c)). The procedure is summarized in Fig. 8.

Determining the ''density'' of produced fragments is conventionally performed by ''box analysis.'' The bands of interest are inspected by the researcher using imaging software and manually ''boxed-in'' with a rectangle or polygon by manual action of the computer mouse. The intensities of each pixel are integrated and the total intensity of the boxed area is calculated (Fig. 8, Panel (b)). The bands in a row (belonging to a specific position in the sequence) in different columns (which are different condition of the experiment) are assembled and converted to fractional saturation $\overline{Y}$. Fractional saturation $\overline{Y}$ is the fractional extent of observed intensity normalized to the defined endpoints such as the intensity of the control lane with no protein is assigned as $\overline{Y} = 0$ and the intensity of a lane with protein at saturating concentrations is assigned as $\overline{Y} = 1$. Before the calculation of $\overline{Y}$, the data need to be ''standardized.'' Standardization is the process that converts the arbitrary intensity to a relative value using a reference band in the same lane. The reference band should be chosen such that it should not change as a function of the experimental conditions. In Fig. 1, the reference band would be ''outside'' of the binding site. This standardization corrects for lane-to-lane variations due to differences in the amount of sample loaded (pipette error, precipitation yields etc.). In order to fit the plotted data set, isotherms or progress curves are generated using $\overline{Y}$. The calculated data set is fitted by the mathematical model that explains the phenomenon best. The Hill equation is commonly used for equilibrium ligand–binding studies. Two parameters are calculated in the Hill equation. The

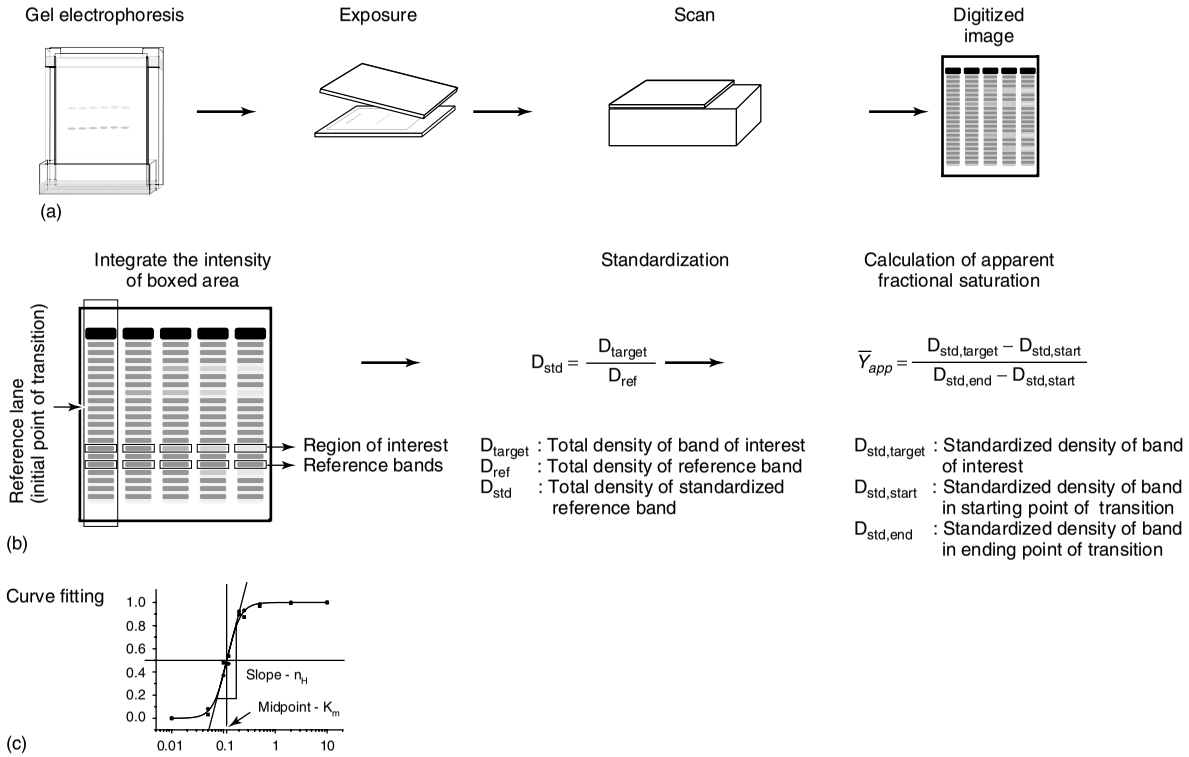

Fig. 8 Typical procedure for footprinting experiments. Panel (a): electrophoresis and scanning image. The ^{32}P-labeled sample is electrophoresed using sequencing gels (for better resolution), then dried and exposed to the imaging plate. After exposure, the imaging plate is scanned and the digitized gel image is generated. Panel (b): Data conversion: the digitized gel image is quantitated using densitometric software. The "Box analysis" or "single-band analysis" can be used for the quantification of the bands. By this procedure, the total intensities of the bands are converted to numerical data. The "standardization" within the lane is a process that eliminates the difference in loading and enables comparisons among the lanes. Fractional saturation is calculated using two endpoints that are the initial state and final state of the transitions. Panel (c): generated sets of fractional saturation values are fitted using the nonlinear regression curve-fitting algorithm, and thermodynamic or kinetic parameters of the transition are calculated.

midpoint reports the ligand concentration required for 50% response. The Hill coefficient indicates the cooperativity of the interaction. Detailed examinations of such thermodynamic and kinetic modeling approaches are provided elsewhere.

One common problem with the above approach that prevents maximal structural resolution from being extracted is that the bands may not be separated completely in the electrophoresis step. The box analysis cannot take into account the effect of overlapping areas and thus is potentially inaccurate. Although in the case of DNA gels, the background is generally low and separation is good, RNA gels can be more problematic. The box analysis can only be applied to very well separated bands or regions for accurate quantitative analysis. Figure 9, Panel (a) shows a typical gel image and the corresponding intensity profile. The minimum points on both sides of each band (peak) are not zero, indicating the overlapped area. To overcome these difficulties, the intensity profile can be fitted with a Lorentzian peak function

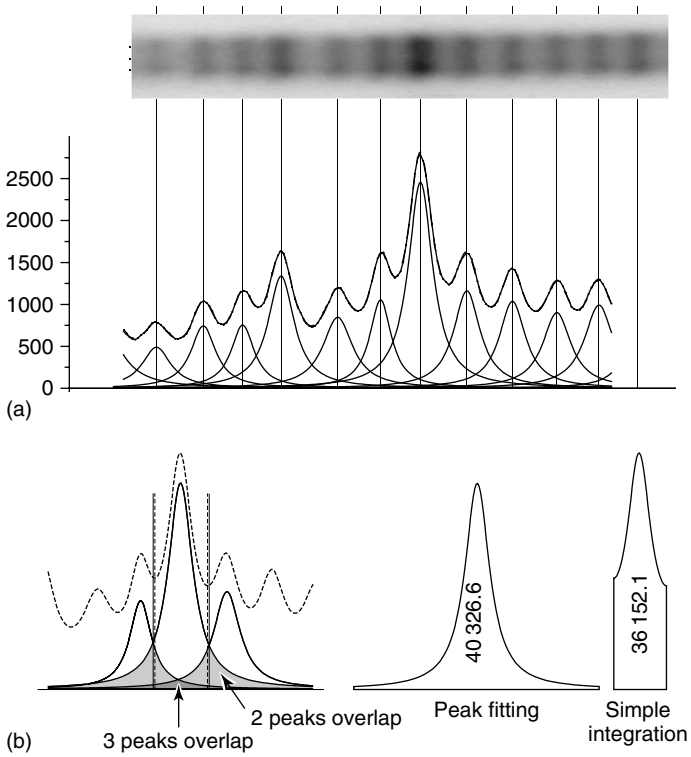

Fig. 9 The effect of overlapped area in total intensity calculations. Panel (a): typical electrophoresis gel image and its intensity profile. The intensity profile is fitted with a set of peak functions (usually Lorentzian). Panel (b): overlapped area and difference in two methods. The ''box analysis'' corresponds to the simple integration between the lowest points of peak. However, there is an overlap among the peaks (bands), which is contributed by bands from both sides. The integrated areas are different by 10% in this particular case.

and peak areas can be calculated (Panel (b)). The simple integration between the lowest positions in intensity gives a peak area of 36 152 while the fitted peak area is 40 326. In this case, box analysis has underestimated the intensity by 10%.

Tullius and coworkers have approached the problem using ''single-band analysis.'' This was further developed for the structural analysis of the *Tetrahymena* group I ribozyme. In this case, the ''single-band analysis'' accurately provided single-nucleotide resolution data for more than 350 residues and gave more precise and detailed information about the tertiary structure formation involved in RNA folding.

Quantitative equilibrium analysis is the means to determine the thermodynamic parameters of binding, complex formation, and folding for nucleic acids. Quantitative DNase I footprinting was achieved and thermodynamic DNA–protein binding models were constructed by Ackers and coworkers. This framework was applied to hydroxyl radical footprinting in order to analyze rRNA structure and DNA conformational changes upon protein binding. Chemical denaturation methods have also been applied to RNA folding and the free-energy change and *m*-values revealed the stability and cooperativity of formation of tertiary contacts.

In addition to equilibrium footprinting, kinetic studies are also important for understanding macromolecular interactions. The first quantitative kinetic footprinting was done with peroxonitrous acid and kinetic DNase I footprinting was subsequently developed. The use of synchrotron X-rays has allowed progress curves for each tertiary contact in *Tetrahymena* group I ribozyme to be examined.

2.5 *In Vivo* Footprinting

In vivo footprinting is of great interest to molecular biologists. Many interactions cannot be reproduced *in vitro* because of the complexity of the cellular environment. DNA is packed in the chromatin and the conformations and environments are often quite different from *in vitro* conditions. The DMS chemical modification method is frequently chosen for *in vivo* footprinting, taking advantage of its small size and permeability to the interior of the cells without special treatments that could cause changes in cellular metabolism or response. $KMnO_4$ can be used as an *in vivo* footprinting reagent for the same reason as DMS. Although multicopy plasmids are relatively easy to detect by this method, detection of chromosomal DNA structure has several difficulties. The copy number is one per cell and there are complex structural arrangements (supercoiling, chromatin). A modified PCR protocol was developed for chromosomal DNA footprinting to enable detection. Recently, Tullius and coworkers explored the use of γ-ray for generating hydroxyl radicals *in vivo*. This is a potentially valuable advantage for *in vivo* footprinting since the radicals will be generated *in situ*.

3 Applications

3.1 Hydroxyl Radical Footprinting of RNA Folding

3.1.1 Thermodynamics

When RNA folds into discrete tertiary structures, regions of the backbone that become inaccessible to solvent are protected

from hydroxyl radical cleavage. Thus, unimolecular as well as bimolecular processes can yield "footprints." The folding of RNA can be monitored nucleotide by nucleotide when the extent of hydroxyl radical reactivity is followed as a function of a thermodynamic variable that shifts the folding equilibrium. This approach was first used to study the Mg^{2+}-induced folding of the *Tetrahymena* ribozyme to its catalytically active conformation.

When measurements are conducted under appropriate conditions, such transitions can yield folding isotherms allowing thermodynamic data to be derived locally within the molecule. For example, in experiments examining the Mg^{2+}-dependent folding of the *Tetrahymena* ribozyme, the isotherms describing the folding of the P4–P6 domain have higher apparent affinity for Mg^{2+} and are less concerted than the transitions within the catalytic core. The linkage of monovalent and divalent ion binding can also be examined with this method. In Mg^{2+}-dependent footprinting experiments on the isolated P4–P6 domain of the *Tetrahymena* ribozyme, direct competition exists between monovalent and divalent ions for sites within the A-bulge, that has been crystallographically shown to specifically coordinate Mg^{2+}, while other regions of the domain were unaffected as shown in Fig. 10.

Another method for examining the stability of RNA combines urea denaturation with footprinting. Approaches originally developed to determine the global stability of proteins have also been applied to RNA. When urea denaturation and footprinting are combined, site-specific unfolding isotherms are generated that can lead to an understanding of both stability changes as well as cooperative coupling within the molecule. For a two-state transition with respect to the specific protections examined, a linear dependence of folding-free energy on urea concentration is fit to the data to determine the folding-free energy in the absence of denaturant, ΔG°_{N-U}, and the sensitivity to urea denaturation, expressed as the *m*-value. This approach allows a quantitative determination of the free-energy differences for the formation of specific protections under different solution conditions or for different RNA sequences, including comparisons of mutant RNA molecules.

The combination of local structural information provided by hydroxyl radical footprinting with global measures of RNA conformation has proven valuable in understanding the processes of RNA folding. For example, hydroxyl radical footprinting of the bI5 group I intron ribozyme in concert with native gel electrophoresis demonstrated that the formation of a nonnative collapsed structure occurs at lower Mg^{2+} concentrations than native tertiary contacts.

3.1.2 Kinetics

The folding of many large RNA molecules is dominated by kinetically trapped intermediates in their folding pathways while other RNA molecules fold without kinetic traps. The development and application of an oligonucleotide hybridization assay presaged time-dependent hydroxyl radical footprinting as an effective probe of the time dependence of the Mg^{2+}-dependent folding of the group I *Tetrahymena* ribozyme. The hierarchy of this ribozyme's folding was observed to extend to the fastest folding events on the millisecond timescale using synchrotron X-ray hydroxyl radical footprinting. These

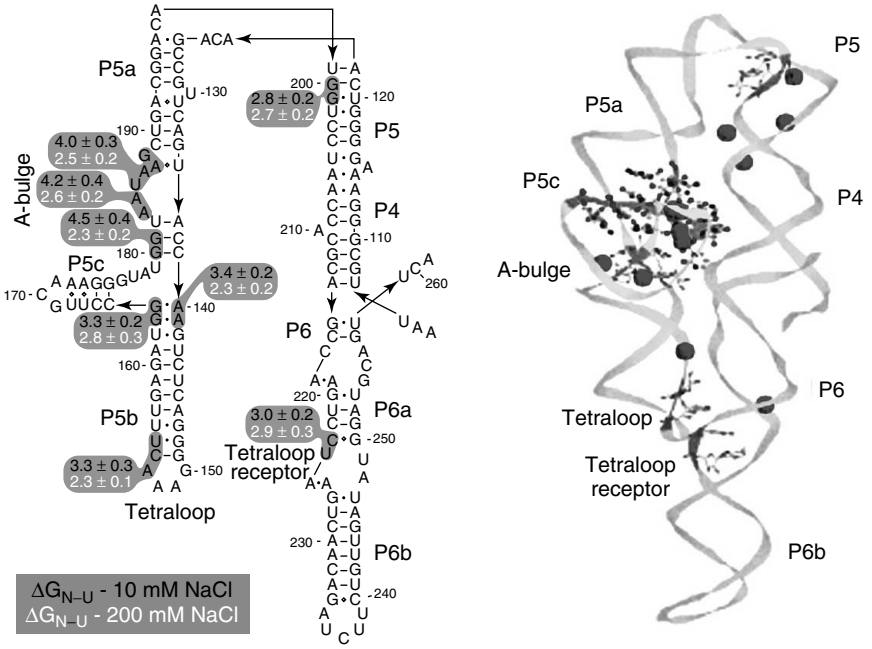

Fig. 10 ΔG°_{N-U} values of P4–P6 domain of *Tetrahymena* group I ribozyme. The hydroxyl radical footprinting experiments in conjunction with urea denaturation revealed the stability difference induced by differences in monovalent cation concentrations. The direct competition between Mg^{2+} and Na^{+} is observed in the region in which Mg^{2+}-specific binding sites are observed in the crystal structure (A-bulge). Modified from Uchida, T., He, Q., Ralston, C.Y., Brenowitz, M., Chance, M.R. (2002) Linkage of monovalent and divalent ion binding in the folding of the P4–P6 domain of the Tetrahymena ribozyme, *Biochemistry* **41**(18), 5799–5806.

studies showed that the native tertiary contacts of the P5c subdomain form first ($\sim 2\ s^{-1}$), followed by the P4–P6 domain ($\sim 1\ s^{-1}$), the peripheral helices ($0.2–0.4\ s^{-1}$), and lastly the catalytic core ($\sim 0.03\ s^{-1}$). These observations led to the novel conclusion that the organization of the catalytic core occurs within the constraints of the organized ring formed by the peripheral helices and P4–P6. Faster folding of the RNA induced by monovalent cation addition was also examined by synchrotron footprinting studies.

Progress curves obtained for the slow folding steps of the *Tetrahymena* ribozyme by time-resolved peroxonitrite footprinting are comparable to those obtained by the X-ray footprinting approach. This group of investigators used the same approach to show that folding of the M1 RNA occurs via the formation of two independently folding domains and that each domain subsequently proceeds through a discrete series of intermediates. Peroxonitrite footprinting was ideal for the kinetic analysis of 32 individual protections following the folding of a group II ribozyme derived from intron ai5γ. All the regions of this ribozyme fold slowly and synchronously on a timescale of several minutes with no evidence of kinetically

trapped intermediate species. These data suggest a folding mechanism in which the rate limiting step is early in the reaction pathway that is very different from the group I ribozymes that have been studied.

Peroxonitrite footprinting has also been used in thermodynamics and kinetics of the Mg^{2+}-dependent folding of the Varkud satellite ribozyme. This ribozyme folds rapidly within 2 s, that is, the first time point of this study while the acquisition of catalytic activity occurs more slowly appearing after 10 min. In contrast, the kinetics of folding of a minimal two-way helical junction hairpin ribozyme studied by Fe-EDTA are slow, requiring ~100 s to reach completion. Complementary time-resolved photo cross-linking studies demonstrated that a conformational change in a tertiary element (the ''loop E-like'' motif) of this ribozyme is coincidental with domain docking. These conformational changes are essential for catalysis.

In summary, chemical and radiolytic methods of hydroxyl radical generation are available that allow footprinting of transitions involving nucleic acid conformational change and ligand binding on timescales of milliseconds to minutes. This approach allows the time dependence of the transitions undergone by complex molecules to be quantitatively monitored with single-nucleotide resolution.

4 Future Prospects

The prospects for footprinting research have never been brighter. A technique that was once the exclusive province of molecular biologists is now a powerful probe for structural biology. Current techniques can monitor nucleic acid structure with monomer resolution and examine the dynamics of conformational changes on millisecond timescales. The growing availability of atomic resolution–structural information from crystallography and NMR studies is allowing footprinting data to be interpreted with increased accuracy and in the appropriate context of the structure. Increasingly, this allows specific structural hypotheses about conformational change and dynamics as a function of ligand binding to be tested using footprinting experiments.

A major advantage of footprinting studies is that the size of the macromolecule is not intrinsically limiting, such that intricate complexes can be examined at high resolution. Macromolecular assemblies control biological processes as fundamental as replication, transcription, translation, as well as many signal transduction pathways relevant to development and cell–cell communication. Cryo-electron microscopy and advanced mass spectrometry techniques are proving valuable in defining the size, shape, and components of such assemblies; it is clear that footprinting data will be used in conjunction with these methods to define the specific sites of important tertiary interactions. The possibility of footprinting *in vivo* provides an exciting prospect that such assemblies can be probed in the native cellular environment, although significant challenges to such experiments are obvious. However, considering the noteworthy progress of footprinting research over the last 30 years, it would not be a surprise to see such studies even 5 years hence. In any case, footprinting will remain a useful tool for structural and dynamics studies of nucleic acids for many years to come.

Acknowledgment

The authors wish to express their deep appreciation to Professor Michael Brenowitz for his many contributions to this work and to footprinting research in general. Financial support has been provided by the NIH through P41-EB-01979 and R01-GM-52348.

Keywords

One-hit Kinetics
A characteristic of cleavage-based footprinting techniques that achieve limited cleavage of the population of macromolecules, such that on average, each molecule cleaved is cleaved only once.

Footprinting
A technique used for probing macromolecular structures and interactions. It relies on the fact that some regions of the macromolecule are buried or become inaccessible as a consequence of their structures/interactions. Enzymes or chemical reagents are used as probes of the structure.

Hydroxyl Radical
Highly reactive and unstable molecular species. Its small size and nondiscriminating reactivity make it an ideal probe for footprinting.

Fenton Chemistry
The most commonly used chemical method to generate hydroxyl radicals. It is based on homolysis of hydrogen peroxide catalyzed by Fe(II) ion. By the reaction, Fe(II) ion is oxidized to Fe(III) ion and regenerated by the reductant (thiols, ascorbate) in the reagent.

Radiolysis
Chemical reaction driven by direct absorption of ionizing radiation energy. Particularly, aqueous solutions in biological systems generate hydroxyl radicals and hydrated electrons through the absorption of ionizing radiation.

RNA Polymerase
Macromolecular complex involved in the gene transcription.

Mass Spectrometry
Method to study proteins or protein fragments using high-resolution mass identification.

Western Blot
Method of molecular identification using antibody recognition and size.

''Footprinting'' refers to assays that examine ligand binding and conformational changes by determining the solvent accessibility of the backbone, bases, or side-chain structures of macromolecules through their sensitivity to chemical or enzymatic cleavage or modification reactions. Protein footprinting methods have been developed to examine protein structure and conformational changes by monitoring solvent accessibility using either modification or cleavage reactions.

Examples of such methods include acetylation, nonspecific limited proteolysis, or probing accessibility of a range of sites that can be specifically or nonspecifically cleaved or modified. The basis of these diverse chemical approaches is to monitor the change in accessibility of susceptible residues as a function of relevant conformational fluctuations. In addition, the amounts of material required for exploring the structure and function of proteins using footprinting is in the femtomole to picomole level for detailed analysis. Protein footprinting methods based on protease cleavage have been used to map protein structure, nucleic acid–protein interactions and protein folding intermediates. However, cleavage techniques using proteases suffer from limited structural resolution due to the large size of the probe. Hydroxyl radical methods of cleavage and modification have been pursued to overcome this drawback. In this article, we document the history of protein footprinting and the development of new technologies based on mass spectrometry to accurately locate and quantify protein structure and conformational changes upon ligand binding.

1
Principle of Protein Footprinting

1.1
Background & History

Understanding the details of protein structure and their interactions in macromolecular assemblies is one of the most important problems in biology. The interactions of proteins and their assembly into large complexes control processes as fundamental as replication, transcription, translation, metastasis, apoptosis, and many other signal transduction pathways relevant to development and cell–cell communication. Protein footprinting approaches, paralleling the successful development of nucleic acid footprinting approaches (*see also* Takamoto and Chance, Footprinting methods to examine the structure and dynamics of nucleic acids), have been developed and refined over the last 15 years in order to provide the molecular details of these interactions and their dynamics.

''Footprinting'' refers to assays that examine ligand binding and conformational changes by determining the solvent accessibility of macromolecules through their sensitivity to chemical or enzymatic modification and cleavage reactions. A fundamental feature distinguishing footprinting from other techniques is the covalent modifications of the macromolecule that are essential to probing the solvent accessible sites. These irreversible changes to the macromolecule can negatively influence the experimental results unless sufficient care is taken in experimental design and analysis. Fortunately, during the 25 years of successful development of macromolecular footprinting approaches, a number of basic principles and control experiments have been established that have allowed the successful examination of structure and dynamics for a wide range of protein and nucleic acid systems, as illustrated in the thousands of footprinting publications that have appeared in the literature.

The initial approaches to examining the specific interactions of macromolecules from the standpoint of either proteins or the nucleic acids were of two types: the first

involved cleavage of the macromolecule followed by a readout of the cleaved fragments and the second, the covalent modification of the macromolecule and analysis of the modified products. In each case, the footprint represents the differential reactivity of accessible sites compared to those that are buried within the structure. For nucleic acids, the first cleavage-based methods that were developed were enzymatic, and involved isolation of a fragment of DNA that was ''protected'' from nuclease digestion due to its binding to a specific protein. Footprinting using chemical modification was developed shortly thereafter; the ligand-induced protection of nucleic acid from methylation was used to map protein–DNA interactions. These approaches evolved into the explicit implementation of (nucleic acid) cleavage-based footprinting that closely resembles the approaches in use today. These footprinting experiments rely on limited cleavage of the backbone (where each position along the backbone is sampled with equal probability) and the ability to uniquely identify the distinct cleavage products so that multiple sites could be individually measured.

Paralleling the approaches pioneered for nucleic acids, the first explicit implementation of protein footprinting used enzymatic cleavage of the macromolecular backbone to probe the contact interface between a protein and its ligand, in this case the interaction of an antigen–antibody complex. Monoclonal antibodies interact with specific epitopes and the antibody–antigen interactions were shown to protect these specific binding sites from protease cleavage. Different proteases were used to probe different sites within the antigen depending on the sequence specificity. In addition, the authors detected antibody binding–induced conformational changes in the antigen, demonstrating the power of footprinting techniques to, in principle, probe sites throughout the macromolecule. A drawback of this particular experiment was that [35-S] methionine labeling was used to label the antigen; this labeled methionines throughout the sequence and the cleavage products generated fragments that could not be uniquely identified by size. Refinements of this method were introduced. In these cases, the end-labeling allowed the unique identification of the fragments. Footprinting of proteins by chemical modification was refined. This method mapped the solvent accessibility of lysine residues by determining their reactivity to modification by acetylation. Although these two approaches incorporated fundamental features of footprinting, it should be noted that methods to modify proteins and probe their structure (originally using diazonium salts) are nearly 100 years old. In addition, specific methods to use modification reagents to map ''buried'' versus ''free'' histidine side chains go back almost 40 years. However, these modification methods primarily evolved into approaches to generate specific sites within proteins that were optically active so as to probe conformational changes using the covalent adducts.

Nevertheless, the modification and cleavage approaches outlined above fit the definition of ''footprinting'' for the purposes of this article, and they illustrate the two distinct approaches that are commonly used. Although the methods outlined above are valuable, additional footprinting assays have been developed using a number of additional approaches. In particular, some of the drawbacks of a number of chemical and enzymatic footprinting reagents include preference of a footprinting reagent for specific positions

within proteins, limiting the number of sites that can be probed. For example, proteases are often quite specific and cut only at a subset of the positions along the protein sequence. Also, the size of proteases, which often can be of the same size as the ligand, can result in an overestimation of the size of the protected region, as well as be blind to any variations in reactivity within the binding site. Modification methods in which lysine is acetylated are suitable for probing accessible lysine side chains, but cannot probe at other sites. Chemical proteases, if they are small, can provide enhanced structural information compared to enzymatic proteases. For example, CNBr can cleave at methionine sites and thus its cleavage products are sensitive to burial of methionine residues. However, the most effective chemical protease and the one in widespread use is the hydroxyl radical (**.**OH), which is commonly generated by the Fenton–Haber–Weiss reaction using Fe(II)-EDTA. It was shown that hydroxyl radicals could provide a relatively nonspecific probe of protein structure and map the sites of protein-DNA binding. The use of hydroxyl radical–based cleavage has the advantages of not only a small size of the probe but also a relatively nonspecific cleavage activity, maximizing the number of potential sites along the backbone that can be probed. However, the use of tethered sources of hydroxyl radicals, which generate the radicals at defined sites, has also proven to be a powerful approach in defining protein–protein interfaces and specific sites of interaction. Hydroxyl radicals have also been developed as side-chain modification reagents, and this approach has been coupled to proteolysis and mass spectrometry techniques to precisely map the modification sites.

1.2 Fundamental Features of Footprinting Methods

The key publication in *Nucleic Acids Research* that has critically influenced the field of footprinting was entitled ''DNase footprinting: a simple method for the detection of protein–DNA binding specificity.'' Aside from popularizing the term *footprinting*, the paper carefully laid out many of the basic principles of the method that are common to all successful footprinting approaches today. The first to be examined was the principle of limited cleavage of the macromolecule. The authors examined the cleavage of labeled DNA fragments (the macromolecule) as a function of incubation time with DNase I (the cleavage agent), and upon examining the fragment distribution, determined that a limited incubation time was optimal. If the incubation time was too short, there was insufficient cleaved material to detect the products. If the incubation was carried out for an extended time, the population of smaller fragments was emphasized, skewing the distribution and depleting the number of larger fragments. This ''one-hit'' kinetic regime was ''the condition in which those fragments produced have a high probability of coming from a single cut of the original piece of DNA.'' This assured a broad distribution of the fragments. For footprinting methods relying on the cleavage of proteins, these principles apply as well. The principle of limited cleavage also provides for the probing of an intact, biochemically relevant population of molecules. The second principle was that of quantitative analysis of the differential reactivity of the distinct sites within the macromolecule, ultimately suggesting the ability to probe, and the value of probing, each and every site. It was

presumed that chemical reaction kinetics would govern the production of cleaved fragments, and that the differences in the extent of reaction of the cleavage agent with a number of specific sites as a function of added protein should be measured quantitatively. The ability to quantitatively measure the individual sites was critical to the analysis. Thus, this paper established the two principles of *limited dose* and *differential reactivity of individual sites* that are fundamental to all footprinting experiments today.

2 Techniques

2.1 Cleavage-based Protein Footprinting

The demonstration of cleavage-based footprinting methods for nucleic acids inspired similar methods to be developed for the analysis of proteins. Initial approaches to examining protein structure and interactions utilized proteases or other cleavage-based reagents (like hydroxyl radicals) in order to assay the solvent-accessible sites. The experimental steps are as follows. Proteins are labeled at one end (see below) and then are subjected to the cleavage agent. The cleavage products are assayed for size by SDS-PAGE (Fig. 1). For nonspecific cleavage, solvent-accessible sites throughout the macromolecule would be sensitive to cleavage, in principle be probed, and would provide a wide range of fragments. One fundamental difference between footprinting studies of DNA and proteins is that for DNA, since the backbone is on the outside of the canonical helical structure, almost every site is potentially accessible. For proteins, the backbone may be buried on the inside of the molecule for much of the structure so the number

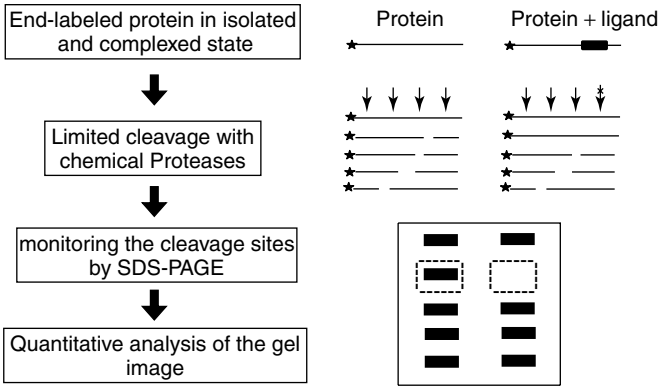

Fig. 1 Schematic representation of cleavage-based protein footprinting. A protein is specifically end-labeled and then subjected to limited cleavage under single-hit conditions in the presence and absence of the ligand. The cleavage products are then separated by size using high-resolution SDS-PAGE, followed by quantitative analysis of a digitized gel image. After correction for protein loading or cleavage-efficiency differences, intensities of corresponding bands in the lane with and without the ligand are compared to get information about the changes in susceptibility to cleavage as a result of ligand binding.

of potential cleavage sites are lessened. Thus, the resultant data will not cleave at each and every monomer position. However, sites on the ''inside'' are not likely candidates for the binding of a ligand such that the impact of this ''disadvantage'' is lessened. In addition, the variation in cleavage across the macromolecular sites interrogates the protein's tertiary structure. When a ligand binds to the protein, accessible cleavage sites on the macromolecule may experience reduced reactivity at the interface (Fig. 1). Many sites should remain unchanged, but allosteric interactions could increase or decrease the solvent accessibility at other sites throughout the macromolecule as well.

2.1.1 **End-labeling Procedures**

End-labeling is required if SDS-PAGE is to be used to separate the cleavage fragments for analysis. The most common methods of end-labeling are specific antibody binding to either terminus or phosphorylation. This end-labeling is advantageous for two reasons. First, it simplifies the identification of the fragments on the gel. For example, when a cleavage event occurs, it naturally creates two pieces. If end-labeling is used, only the fragment retaining the end-label is seen on the gel. One can then immediately identify the site of the cleavage based on the length of the observed fragment. Second, the end-labeling methods generally enhance the sensitivity of the assay, Western blotting (for antibody identification) or autoradiography (for P-32 end-labeling) have vastly increased sensitivity compared to gel staining methods. Use of antibodies requires either a specific antibody to either end of the protein to be available (or to be generated) or the addition of a specific epitope, for which a commercial antibody is available, to either end of the protein. This epitope can be engineered as part of a fusion protein purification strategy, for example, for His-tagged proteins commercial anti-His tag antibodies are available. Phosphorylation at either terminus can be used which is based on the sequence specificity of protein kinases. A phosphorylation sequence (like HMK or FLAG) that can be phosphorylated by a specific kinase is added to the end of the protein at the gene level.

2.1.2 **Protein Cleavage**

Protein cleavage is accomplished either by enzymatic or chemical means. Enzymes to cleave proteins have widespread and variable specificity. To achieve cleavage at a wide range of sites using a protease, a ''cocktail'' of several proteases is useful. However, the protease method has the ultimate drawback that the enzyme is large and may not be sufficiently sensitive to accessibility of the structural backbone to accurately probe the structure. As in the case of nucleic acids, the advent of the use of hydroxyl radicals enhanced the structural resolution of the technique considerably. Hydroxyl radicals have been used both free in solution, where they probe the entire molecular surface, and tethered to specific probe sites, or to sites throughout the macromolecule. A tethered source of hydroxyl radicals provides a cleavage agent with a defined radius of action, generally 10 to 15 Å. In the case of tethering to a wide distribution of sites, it has been found that if the tethers are linked to one molecule in a pair of interacting molecules, the target cleavage sites are localized close to the interacting surface of the binary partner. Thus, the modulation of reactivity ''observed'' in the hydroxyl radical assay can be dissected into the allosteric effects (which are observed

in addition to the effects of burial of the interface when ''free'' radicals are used) and the formation of an interface (which are observed in the experiment with tethered sources of radicals).

2.2 Modification-based Protein Footprinting

As outlined above, it was demonstrated that specific amino acids, like lysine, can act as the footprinting targets for protein footprinting. A protein tagged at one particular end, in both isolated and complexed states, is first treated with a reversible lysine reagent. At this stage only those lysines in a protein that are accessible to the reagent are modified. The protein is then unfolded and treated extensively with an irreversible lysine reagent to block those lysines that did not react previously, followed by reversing the first lysine modification. A lysine-specific endoproteinase is then used to cleave the tagged protein at the deblocked lysines. Separation of the proteolytic products by size and identification of the tagged fragments map the positions of these lysines. As above, gel-electrophoresis methods were used to map the susceptible sites. This provides a way to identify the lysines in a protein that react differently to the reversible reagent when the protein is free by itself and when it is present in a complex. This method takes advantage of the abundance of lysines in many proteins and the tendency of lysyl groups to be located on surfaces rather than in the interior, making lysyl groups attractive targets in probing protein–protein interactions. The lysines of a viral topoisomerase that were involved in intermolecular contacts with DNA were specifically mapped in this work. Hanai has also pointed out that many reagents available for the modification of proteins that were developed in the 1960s and 1970s could be ''revived'' to be used in footprinting assays. In fact, a number of novel approaches to modifying the backbone and specifically incorporated side-chain groups have been developed and successfully applied.

Another approach that has been recently developed is to use chemical modification reagents that are less specific to provide footprinting approaches. It has been well known for some time that hydroxyl radicals, besides generating backbone cleavage events, modify the side chains of proteins quite efficiently. Sulfur-containing, aromatic and aliphatic side chains provide targets that are more sensitive to attack than the protein backbone. Thus, these events are more frequent than the abstraction of the C-α carbon that is the first step in hydroxyl radical–based protein cleavage. The ability of side chains to be modified was combined with mass spectrometric detection to develop a protein footprinting technique. Hydroxyl radicals, as a reagent for footprinting, can be derived from Fenton reagents or from radiolysis sources. In the former case, the Fenton reagent induces a metal catalyzed reaction of hydrogen peroxide to produce hydroxyl radicals. In the latter case, ionization of water produces hydroxyl radicals directly.

The development of the hydroxyl radical as a modification reagent for footprinting and its application in conjunction with mass spectrometry was directly inspired by the development of deuterium exchange mass spectrometry methods. In these approaches, the protein of interest is subjected to a pulse of deuterium intended to label the structural regions that are solvent-accessible and to monitor changes in accessibility in response to the binding of a ligand. After solvent

labeling, the reaction is quenched, the protein is fragmented by proteolysis, the peptide fragments are separated by high-pressure liquid chromatography (HPLC), and mass spectrometry analysis is performed. Peptide fragments with increased mass, relative to control experiments without addition of deuterium, indicate *specific segments* that were solvent accessible and exchange competent during the deuterium pulse. The method used to minimize back exchange during the analytical steps is lowering the pH to ~2.5, thus only proteases with activity at acid pH (e.g. pepsin) can be used to fragment the protein. Although recent, column based, proteolysis methods have decreased the time required for this step, the back exchange is limiting.

Hydroxyl radical–mediated protein footprinting is similar. The overall method is outlined in Fig. 2. In this case, the protein solution is exposed to ionizing radiation and the hydroxyl radicals covalently react with surface-accessible residues, primarily side-chain groups. As in the deuterium exchange methods, the protein is subjected to proteolysis. However, in contrast to deuterium exchange, the production of stable modifications through hydroxyl radical exposure allows a wide range of samples as well as proteases to be used to fragment the protein under a wide range of solution conditions and pH values. Also, the stable modification of side chains allows a specific probe site to be identified using tandem mass spectrometry methods, while for deuterium exchange, typically the conformational change can only be localized to the specific peptide fragment. The drawback is that if a reactive side chain is not present in a particular peptide segment, there are no probes. However, the examination of side chains is complementary to the deuterium exchange method that examines backbone structure. Typically, 30% of the side-chain residues can be probed in a hydroxyl radical–mediated protein footprinting experiment (based on predicted sequence coverage of eight typically used residues – Met, Cys, Trp, Tyr, Phe, His, Pro, Leu). In addition, the use of mass spectrometry can uniquely identify the specific peptide fragments, such that the reactive sites can be easily identified.

To generate the limited dose required for footprinting and to quantitatively examine the reactivity of the specific peptides in question, a series of samples are exposed to variable doses, the samples digested and the individual peptides analyzed by HPLC and mass spectrometry (Fig. 2). Thus, a dose-response curve is generated for each peptide of interest; this generates a quantitative biophysical measure (based on the observed rate of modification) of the relative reactivity of the sites in the different peptides. Consistent and reliable quantitation, which is essential to footprinting, is provided by measuring the relative amounts of the modified and unmodified peptide products in the same experiment. Since the modifications are stable, it is relatively straightforward to use tandem mass spectrometric methods to specifically identify the amino acid positions of the protein that have been modified (bottom right of Fig. 2); these represent the probe sites for the analysis.

In the right-hand side of Fig. 2, where the reaction is carried out in the presence of a protein–protein complex, modification is suppressed at the site corresponding to the interacting surface, and unchanged at sites distal to the contact. The decrease of reactivity of peptides in the interface is quantitatively measured using the dose-response curves, a sample dose response for a peptide whose reactivity is suppressed

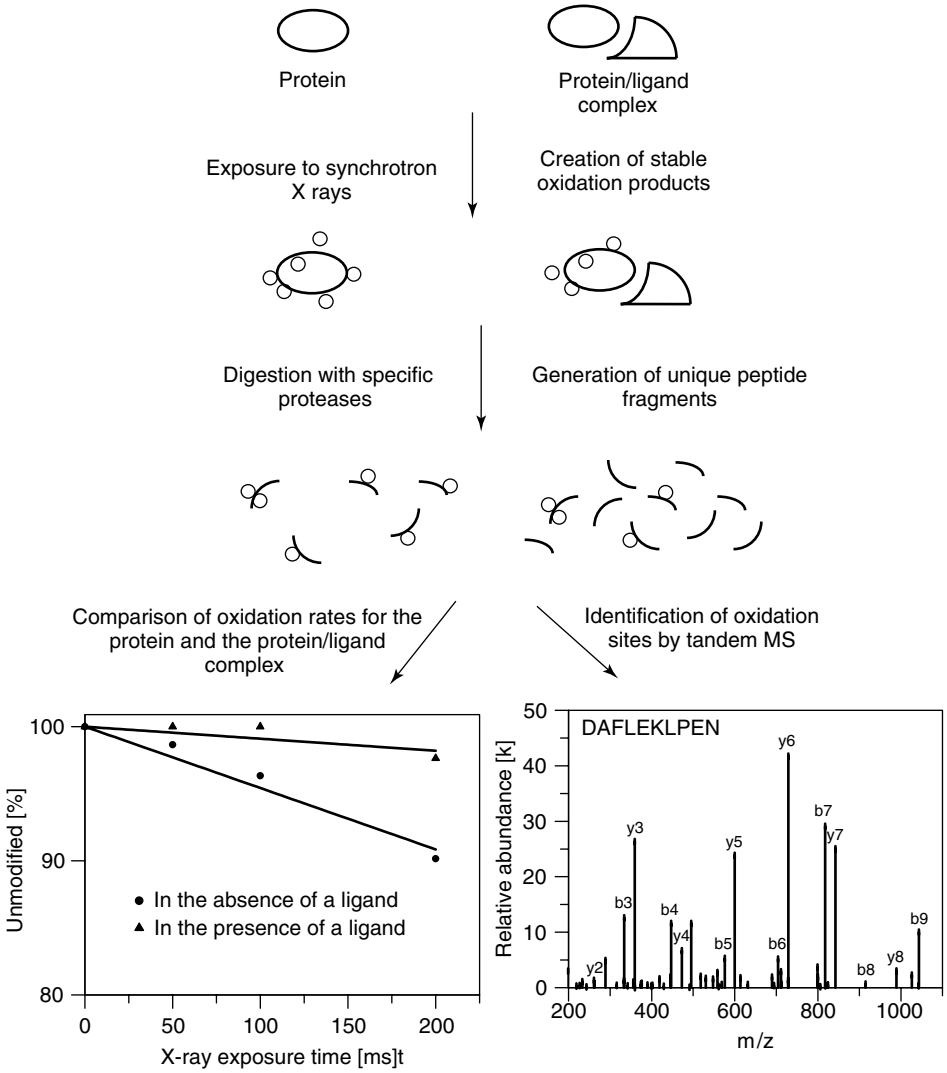

Fig. 2 A schematic representation of hydroxyl radical footprinting. A protein and its complex with a ligand are exposed to radiolysis or Fenton reagents, which produce hydroxyl radicals that modify the side chains of the protein. Subsequent to this X-ray exposure, the protein samples are digested with proteases, and MS is applied to quantitate the extent of modification. This quantitation provides information about the solvent accessibility of each peptide in both the isolated and complexed states. The particular modification sites are determined by tandem MS (MS/MS). In the dose-response example, a slower rate of modification is seen for the peptide when isolated from the complex compared to the case for the free protein. Thus, it is indicated that this peptide contains reactive side-chain residues influenced by the binding process. (Guan et al., 2002)

in the presence of the ligand is shown at the bottom left of the figure. It is critical for the method that the dose-response curves indicate a linear regime extrapolated to zero fraction modified – this assures that the reactivity of particular sites are not changing due to the oxidation process itself. This is a fundamental tenet of footprinting that the probed population is structurally intact. Also, the method of examining loss of the unmodified fraction emphasizes the interrogation of intact material. Although these particular refinements are unique to the hydroxyl radical–mediated protein footprinting approach, they are derived from a detailed knowledge and respect for safeguards that have evolved throughout the long history of development of ''footprinting'' research; such safeguards assure that the structural and biochemical information provided by footprinting methods are reliable. It must be emphasized, however, that footprinting provides only ''local'' information about the reactivity of the side-chain probes. Allosteric changes in conformation induced by ligand binding can also give rise to either protections (decreases in side-chain reactivity) or enhancements (increases in reactivity), depending on the induced conformational changes. This must be carefully borne in mind when interpreting data from these experiments, and examples of each of these are provided in the next section.

3 Applications

3.1 Quantitative Equilibrium Footprinting

Quantitative footprinting using protease cleavage has been developed to study calmodulin (CaM). Calmodulin is a small and highly acidic protein that consists of two homologous domains, which are connected by a flexible central linker. Each half-molecule (domain) contains a pair of calcium-binding sites in a helix–loop–helix or EF-hand motif. CaM binds calcium ions with positive cooperativity and generally activates target enzymes by binding to them in its calcium-saturated form and relieving their self-inhibition. The helix pair movements are accompanied by dramatic changes on the molecular surface of the protein, providing ideal targets for footprinting. Proteolytic footprinting has revealed the Ca^{2+} dependent changes of CaM and functional mutants. This work not only illustrates the susceptibility changes of different sites of CaM during the titration process but also provides direct information about the biological effects of mutation on CaM. For example, it was shown that the mutation E140Q reduces the binding affinity of sites at the C-domain, and sites in the N-domain saturate at a lower level of calcium than those in the C-domain in this mutant (Fig. 3(a)). The effect of this mutation is so severe that complete protection requires 100 μM calcium, 10 times higher than normally observed. Fluorescence studies support these data. By using the same approach, the Ca^{2+}-induced structural alternations of CaM in the presence of trifluoperazine (TFP), an antipsychotic drug that acts as a CaM antagonist, have also been probed. In the absence of TFP, chymotrypsin footprinting of a calcium titration of CaM shows several classes of cleavage probed by chymotrypsin: some positions are susceptible in the absence of calcium and become protected by calcium binding, whereas others are cleaved only at intermediate

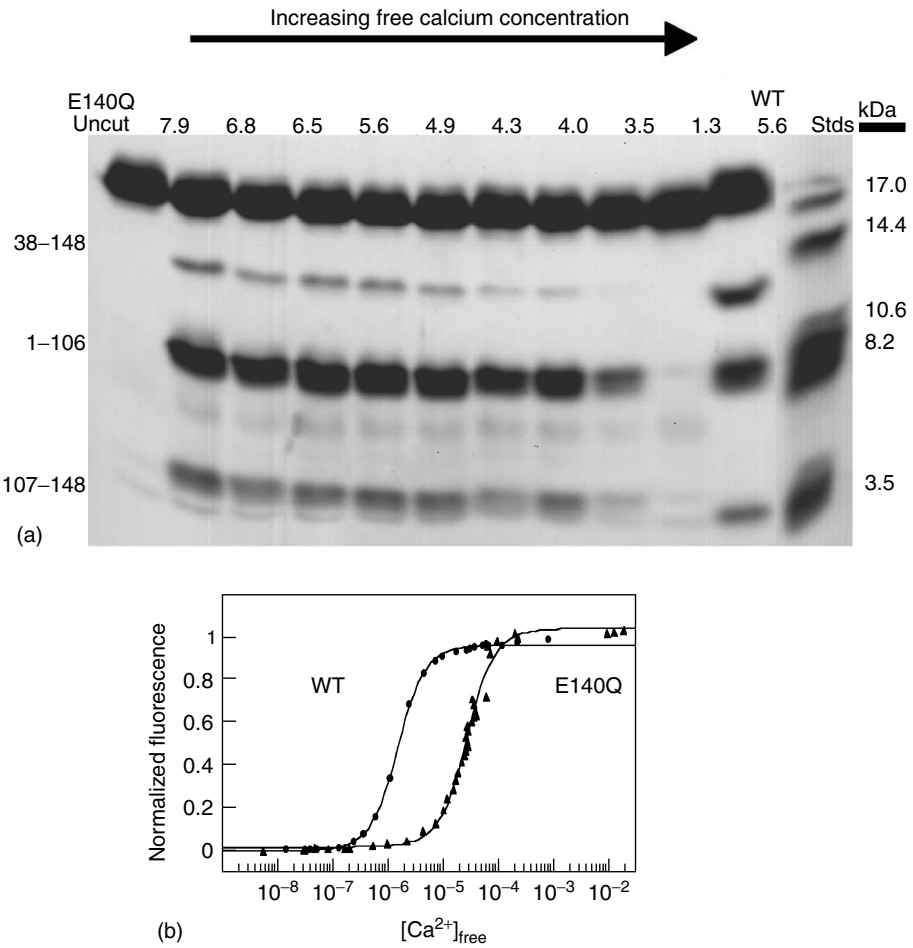

Fig. 3 Proteolytic footprinting can not only illustrate the susceptibility changes of different sites of a protein but can also provide direct information about the biological effects of mutation. Footprinting of CaM shows that a mutant E140 has significant site-specific effects on the binding of Ca^{2+} to CaM. This mutation dramatically reduces the binding affinity of sites at the C-domain, and the sites in the N-domain saturate at a lower level of calcium than those in the C-domain. (a) SDS-PAGE analysis of thrombin-cleaved E140Q-and WT-CaM in 50 mM HEPES, 100 mM NTA, 0.5 mM EGTA, pH 7.4, 25 °C. Lane 1: uncut CaM; Lane 11: products of thrombin footprinting of WT-CaM at pCa 5.6 for comparison of migration of fragments. Lane 12: MW standards. (b) Fluorescence analysis of calcium binding to WT- and E140Q-CaM in HEPES buffer (50 mM HEPES, 100 mM KCl, 0.5 uM NTA, 0.5 mM EGTA, pH7.4, 25 °C). (Shea et al., 2000)

levels of calcium binding. TFP protects CaM from proteolysis even under zero Ca^{2+} concentration, where the C-domains of CaM is normally susceptible. In the presence of TFP, a fragment that has a mass close to that of a half-molecule (a cleavage between the two domains) becomes protected as the concentration of calcium increases. It is necessary to conduct parallel proteolytic footprinting

titrations with multiple proteases to prove that any unusual susceptibility profiles reflect ligand-induced structure variations in the protein; thrombin and chymotrypsin are most frequently used as the proteases.

Modification based quantitative footprinting techniques also have been developed. Synchrotron X-ray protein footprinting has been used to monitor the equilibrium unfolding of proteins. After X-ray exposure, a quantitative map of the oxidized amino acids is generated to determine the relative solvent accessibility of the reactive residues. During folding, amino acid side chains of a protein undergo substantial changes in solvent accessibility that should attenuate the extent of their reaction with hydroxyl radicals in solution. By measuring the changes in reactivity and the degree of modification at amino acid side chains as a function of chemical denaturant concentration, the unfolding of apomyoglobin structure was monitored. It was shown that many of the residues within the hydrophobic core exhibit the expected, highly cooperative, two-state-unfolding behavior, while some residues within helix-G unfold locally and exhibit a lower free energy of stability. The results are fully consistent with those from fluorescence and NMR data.

This technique has been very recently extended to monitoring the structural alternations of gelsolin induced by Ca^{2+}. Gelsolin is a Ca^{2+}-dependent actin-regulatory protein composed of six homologous subdomains (S1–S6) that severs actin filaments and caps the fast-growing barbed end with high affinity. The inactive Ca^{2+}-free form of gelsolin exhibits a remarkably compact structure, in which the N-terminal (S1–S3) and C-terminal (S4–S6) halves are joined by a long linker and form an extensive interface (Fig. 4). Binding of Ca^{2+} to gelsolin and the Ca^{2+}-induced structural reorganization of gelsolin are associated with the actin-binding and actin-severing activity of gelsolin. However, only modest structural information is available regarding the Ca^{2+}-induced reorganization accompanying gelsolin activation. Synchrotron protein footprinting was applied to monitor the structural changes of gelsolin. Of the 81 tryptic peptides of gelsolin, 22 showed oxidation and 59 showed no oxidation upon radiolysis. Of the 22 oxidizable peptides, 5 exhibited a Ca^{2+}-dependent enhancement in oxidation rate, whereas 2 exhibited a Ca^{2+}-dependent protection. Ca^{2+}-titration isotherms monitoring the oxidation within residues 49–72 (within S1), 121–135 (S1), 162–166 (S2), and 722–748 (S6) indicate a three state activation process with an intermediate that was populated at a Ca^{2+} concentration of 1–5 μM that is competent for capping and severing activity. A second, structural transition with a midpoint of ~60–100 μM, where the accessibility of the above four peptides is further increased, is also observed (Fig. 5). The buried residues within the helical ''latch'' of S6 that contact an F-actin binding site on S2 and buried F-actin binding residues within S2 (Fig. 4), are unmasked in the sub-micromolar transition (Fig. 5). However, residues within S4 that are part of an extended β-sheet with S6 are revealed only in the subsequent transition at higher Ca^{2+} concentrations (Fig. 4); the disruption of this extended contact between S4 and S6 (and likely the analogous contact between S1 and S3) likely results in an extended structure permitting additional functions consistent with the fully activated gelsolin molecule. In summary, it has been demonstrated that protein footprinting is a quantitative biophysical

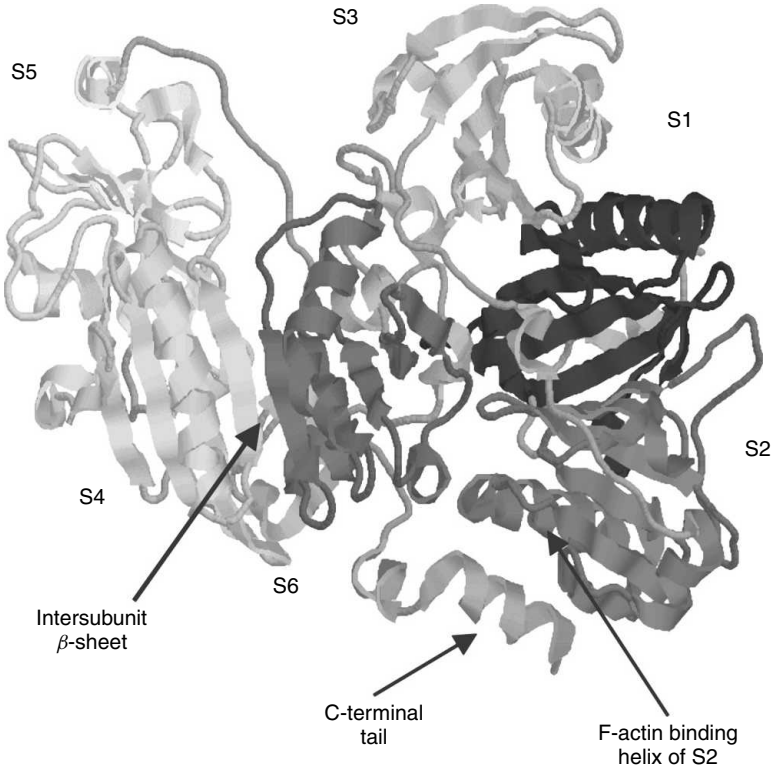

Fig. 4 Subunit structure of gelsolin (S1–S6). The inactive Ca^{2+}-free form of gelsolin exhibits a remarkably compact structure, in which the N-terminal (S1–S3) and C-terminal (S4–S6) halves are joined. The N-terminal half severs actin filaments through a mechanism that involves side binding through S2. The helical tail of S6 interacts with the F-actin-binding helix of S2 to make its actin-binding sites inaccessible in the absence of Ca^{2+}. Also, the intersubunit β-sheet between S4–S6 and S1–S3 must be sheared to provide for maximal Ca^{2+} loading. (Kiselar et al., 2003)

technique capable of probing differential responses of protein subdomains to ligand binding.

3.2 Footprinting of Complexes

Like gelsolin, cofilin is another actin-regulatory protein that binds to both monomeric and filamentous actin. Although crystal structures for the monomeric forms of both G-actin and cofilin have been described, the structure of the binary cofilin/G-actin is not available. Using synchrotron protein footprinting, the G-actin binding sites on cofilin has been probed. It was found that residues within peptides 4–20, 10–17, 83–96, 91–105, and 106–117 of cofilin exhibit strong protection upon G-actin binding. Specifically Leu13, Pro94, Met99, Leu108, and Leu112 define a binding surface consisting of helix α3 and N-terminal segments. These results are supported by previous

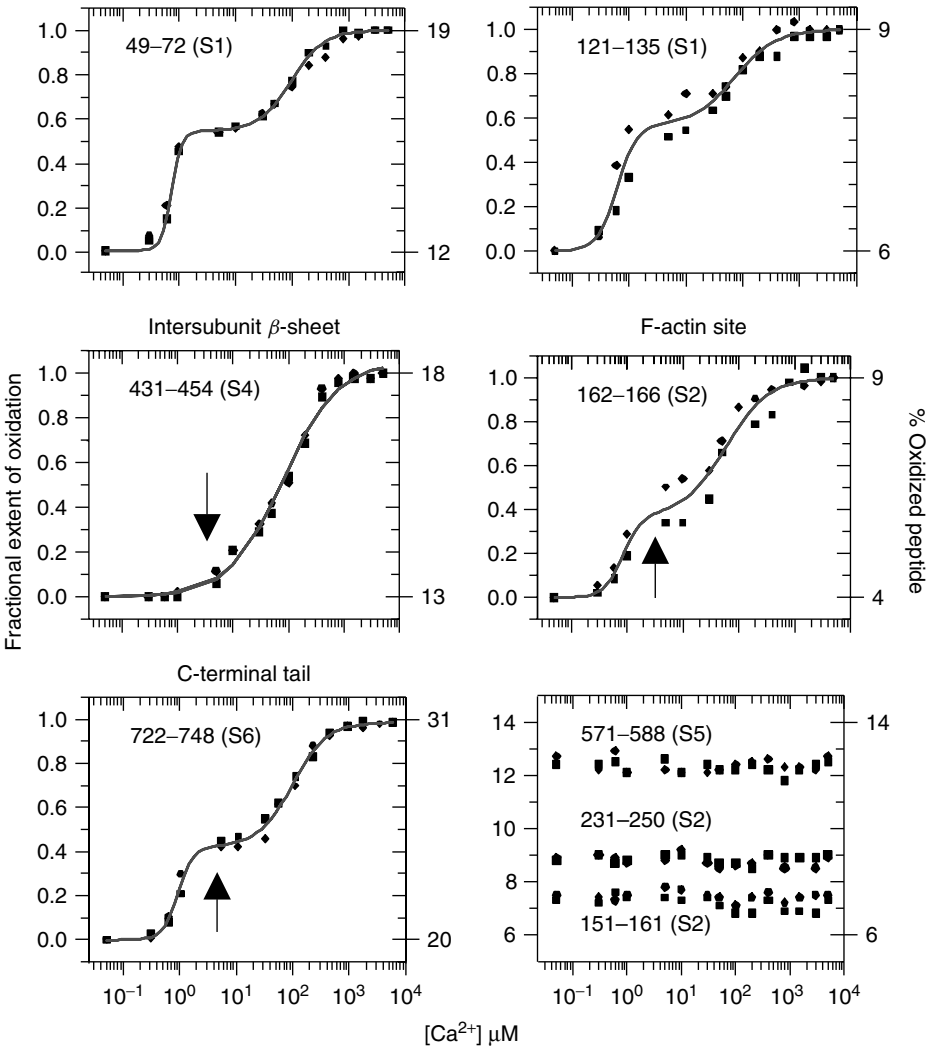

Fig. 5 Ca^{2+} titration isotherms indicating changes in oxidation extent for specific peptides after exposure of gelsolin to the X-ray beam for 80 ms. The percentage of oxidized peptide is shown on the right side of the *y*-axis; on the left side, the transition extent is indicated. The solid lines represent the fitting of the curves using appropriate one or two state Hill functions. Oxidized peptides within gelsolin show no changes in oxidation upon titration by Ca^{2+}. (Kiselar et al., 2003)

mutagenesis studies, which showed Arg96 and Lys98, Ser103 and Ser104 (corresponding to residues 119 and 120 from porcine cofilin) are important for both F- and G-actin binding. In addition, the footprinting studies indicate that peptide 106–117 is protected, consistent with recent work in which mutation of R109 to A and R110 to A were shown to reduce G-actin binding. Although the N-terminal

region of cofilin has been suggested to be essential for both G- and F-actin binding, including residues 1–4, the exact binding sites in the $\alpha 1$ helix have been unclear. It has been shown that the binding surface extends to Leu13, but does not include Leu21. In addition, the X-ray footprinting results suggest that the entire cofilin $\alpha 3$ segment contributes to the actin binding surface. Furthermore, the data suggests that the binding surface extends to Pro94, which is the residue prior to the start of the $\alpha 3$ helix.

Progress in footprinting protein complexes has also been made by designing unique sites in proteins at which a small reagent with cleavage activity can be tethered. First, a set of mutant proteins, each of which has a unique cysteine residue at a chosen location for conjugation to the cutting reagent, are prepared. The conjugated protein is then added to a target protein. Upon activation, the tethered cutting agent cleaves close-by segments of the target protein, producing two fragments. The cleavage fragments are separated by gel-electrophoresis, followed by Western blotting and visualized with antibodies against the termini of the target protein. An alternative to the single-cysteine tethered cutting approach involves tagging surface-accessible lysine side chains. These tethered cutting reagents have been used to study the binding sites of σ factors on RNA polymerase (RNAP). The RNAP of *Escherichia coli* is a member of a conserved family of multisubunit RNA polymerases. Core RNAP, which is a noncovalent complex of four proteins ($\alpha_2\beta\beta'$) with 380 kDa, binds to one of seven different σ proteins to form the holoenzyme ($\alpha_2\beta\beta'\sigma$) for RNA synthesis. Tethered cutting reagents attached to the engineered single-cysteine mutants of $\sigma 70$ have been used to identify sites on $\alpha_2\beta\beta'$ near each cutter. The cut sites on *E. coli* RNAP subunits β and β' made by reagents tethered to several different sites on $\sigma 70$ neatly outline a σ-core binding site and the orientation of $\sigma 70$ relative to the core RNAP subunits. Targeted protein footprinting by using lysine-conjugated $\sigma 70$ was shown to be consistent with that using cysteine-$\sigma 70$ mutants. The interaction between *E. coli* $\sigma 70$ and DNA in transcription complexes has also been studied by using tethered cutting reagents in Meares group. As discussed previously, the tethering process localizes the cleavage to the site of protein–protein interaction.

4 Future Prospects

Future development of protein footprinting technologies are focused on examining the structure of large macromolecular complexes, and probing the dynamics of macromolecules. Purification of biophysical quantities of stoichiomeric complexes has allowed the detailed examination of RNA transcription complexes of 380 kDa, and cytoskeletal assemblies like Arp 2/3 of 270 kDa using protein footprinting. Molecular cross-linking strategies will provide useful additional information as well. Other areas of development include using the flux of synchrotron radiation to provide time-resolved probes of protein dynamics, as has been seen in the studies of nucleic acids. An excellent example of the kinds of experiments that would be of interest would explore the timescales of activation of Ca^{+2} sensitive sites within gelsolin. In addition, detailed examination of side-chain chemistries will expand the sequence coverage of hydroxyl radical–protein footprinting. As availability

of new sequences for protein expression increases, structural and proteomic technologies like footprinting will continue to play a key role in understanding protein structure, function, and protein interactions.

Keywords

Autosome
Any chromosome other than the sex (X and Y) chromosomes.

Dynamic Mutation
A multistep mutational process such that the chance of each step occurring is modified by the immediately preceding step.

Fragile X Syndrome
The most common form of familial mental retardation. Affected patients also have subtle dysmorphic features.

Jacobsen Syndrome
A mental retardation/congenital malformation syndrome caused by the loss of part of the long arm of one number 11 chromosome.

Polymorphism
The existence in a population of more than one version of the DNA sequence at any place in the genome such that the rarest version cannot be maintained by mutation alone.

Trinucleotide Repeat
A DNA sequence composed of three nucleotides repeated in tandem a number of times.

1 Definition

Fragile sites are specific points on chromosomes that show nonrandom gaps or breaks when the cells from which the chromosomes have been prepared have been exposed to a specific chemical agent or condition of tissue culture. Hence, a fragile site is an area of chromatin, which is not compacted when viewed in mitosis.

2 Nomenclature

There are two forms of nomenclature used for fragile sites. The cytogenetic nomenclature uses *fra* followed by the chromosome band in which the fragile site is present in parentheses. The rare fragile site in band 23.3 on the long (q) arm of chromosome 11 is thus fra(11)(q23.3). Each fragile site also has a gene symbol and this is *FRA*, the chromosome number, and an assigned letter of the alphabet. Fra(11)(q23.3) is *FRA11B*. The gene symbol is a locus name. Alleles at the locus can be specified following an *, the wild-type allele as N, and the mutant allele as R (for rare) or C (for common), followed by the chromosome band. Fra(11)(q23.3) in gene nomenclature would be *FRA11B*N* for the wild-type allele and *FRA11B*RQ233* for the mutant allele. In practice, the gene symbol is frequently used to specify the mutant allele and the wild-type allele is not mentioned.

3 Classification

Fragile sites are classified on the basis of their frequency in the population and the conditions of tissue culture under which they are expressed. Rare fragile sites are seen at a specific location on 1 in 40 chromosomes at most. Common fragile sites are probably present on all chromosomes and as such are normal components of chromosome structure.

Most fragile sites are not expressed spontaneously but must be induced. When they are expressed spontaneously, the proportion of metaphases in which they are seen can usually be greatly increased by appropriate conditions of induction. The classification, based upon population frequency and induction conditions, is shown in Table 1 and all known human fragile sites are listed in Table 2.

4 Molecular Genetics

4.1 Group 1

Only five of the group 1 fragile sites have been cloned and details of these are shown in Table 3.

The common features of these fragile sites, which are likely to be common to all the group 1 fragile sites include the following:

1. The fragile site is a dynamic mutation of a naturally occurring CCG trinucleotide repeat.
2. The CCG repeat is polymorphic in the normal population.
3. Increases in the number of copies of the repeating unit, above the normal range leads to a premutation. Individuals with the premutation do not express a fragile site. Premutation carriers of the fragile sites on the X chromosome associated with mental handicap do not suffer this problem. But premutation

Tab. 1 Classification of fragile sites.

Rare:	Group 1:	Folate sensitive fragile sites ($n = 22$)
	Group 2:	Distamycin A inducible a) Also inducible by BrdU ($n = 2$, *FRA16B*, *FRA17A*) b) Not inducible by BrdU, and only recorded in the Japanese ($n = 3$, *FRA8E*, *FRA11I*, *FRA16E*)
	Group 3:	BrdU requiring ($n = 2$, *FRA10B*, *FRA12C*)
Common:	Group 4:	Aphidicolin-inducible ($n = 76$)
	Group 5:	5-azacytidine inducible ($n = 4$)
	Group 6:	BrdU-inducible ($n = 7$)

carrier females are at increased risk of premature ovarian failure and males of a late onset (>50 years) tremor/ataxia neurodegenerative syndrome. As the number of copies of the repeating unit increases further, the DNA in the whole area is subjected to CpG methylation. Once this happens, the fragile site can be induced to appear and any gene in which the repeat is located ceases to be transcribed.

For *FRAXA*, the upper limit of copy number in normal chromosomes is about 55; from 55 to about 230 copies constitutes a premutation and beyond 230 is a full mutation. The number of copies changes from generation to generation, usually increasing when transmitted by women but not changing much when transmitted by males (Fig. 4).

The process by which the polymorphic trinucleotide repeat increases from within the normal range to give a fragile site is a multistep one known as *dynamic mutation*. The probability of a trinucleotide repeat changing in length is a function of the number of copies of the repeat that are present without interruption or imperfection. In the normal population, most alleles of the trinucleotide repeat have some imperfections. It is the alleles with the longest stretches of perfect repeat that form a reservoir of alleles in the normal population, which can proceed via dynamic mutation to fragile sites.

Since the length of repeat determines the rate at which further increases occur, the chance of a premutation converting to a full mutation increases with the size of the premutation alleles. This has been studied in most detail for *FRAXA*. For this fragile site, only women have offspring with full mutations. The upper limit of normal copy number is about 55. For women with premutations of less than 60 copies, the risk of having a child with a full mutation is close to zero. (The smallest alleles observed to go to a full mutation in a single generation have had 59 copies of

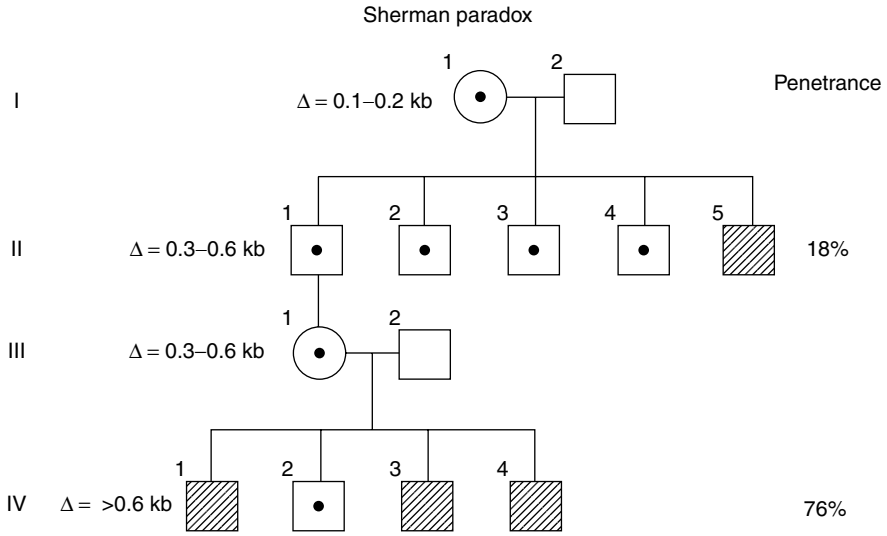

Fig. 1 The Sherman paradox. A hypothetical pedigree is used to illustrate the different levels of penetrance of the fragile X mutation depending upon the position of the carrier in the pedigree. The fragile X carrier I-1 has an 18% chance (approximately one in five risk) that her fragile X sons are affected, while the fragile X carrier III-1 has a 76% chance (three in four risk) that her fragile X sons are affected. The size of the amplification of the fragile X p(CCG)n repeat is given as Δ, that is, for a normal individual Δ = 0.0 kb. Values for Δ indicated are those expected hypothetically for individual 1 in each generation. Hatched squares indicate individual with fragile X syndrome, black dots indicate fragile X transmitters (from Richards and Sutherland 1992).

the repeat.) The chance of 60 to 80 copies converting to a full mutation is about 30%, for 80 to 90 copies it is about 80%, and for greater than 90 copies it is virtually 100%.

The limited numbers of normal alleles with long stretches of perfect repeat that form the reservoir of mutable alleles give rise to the phenomenon of linkage disequilibrium. The distribution of haplotypes around the fragile site locus is very different on normal and fragile site chromosomes.

The place and time of expansion of a full mutation from a premutation is uncertain. Most evidence points to expansion during oogenesis with a period of instability of the expanded repeat during early embryonic development during which period large repeats, in particular, break down to give different cell lineages with different numbers of copies of the repeat. This can manifest as multiple bands or smears on a Southern blot (e.g. Fig. 4, lane 6). As CpG methylation becomes established later in embryonic development, the repeat region is stabilized and further changes in copy number are rare.

The CCG repeats are adjacent to CpG islands and have been shown to be in the 5′-untranslated regions of the genes *FMR1* (at *FRAXA*), *CBL2* (at *FRA11B*), *FMR2* (at *FRAXE*) and *FAM11A* (at *FRAXF*). For *FRAXA*, a full mutation results in cessation of transcription of *FMR1*, and this is the molecular basis of fragile X syndrome; similar is the case for *FMR2* at *FRAXE* and mild mental retardation. *FRA11B* is in the 5′-untranslated region of the *CBL2*

oncogene; genes possibly associated with other cloned fragile sites have not yet been identified.

4.2 Groups 2 and 3

Two rare fragile sites, *FRA16B* from group 2 and *FRA10B* from group 3 have been characterized at the molecular level. Both are expansions of A/T (adenine/thymidine)-rich, minisatellite, DNA-repeat sequences. *FRA16B* is a massive expansion of a 33-bp sequence. Interestingly, this sequence has been reported to be 35-bp in length in a Japanese carrier of this fragile site. This fragile site does not appear to affect any gene and homozygotes have been described who are normal. FRA10B is due to an expansion of a 42-bp AT-rich minisatellite repeat that does not appear to affect any gene; again, homozygotes are normal.

4.3 Group 4

This is the largest group of fragile sites, and the only common ones that have been characterized at the molecular level. They are regions of fragility on the chromosome that extend over hundreds of kilobases of DNA, have no specific sequence features other than being AT-rich with many repetitive elements, and yet have genes within them (Table 4).

5 Cytogenetics

Fragile sites are seen by examining metaphase chromosomes under the light microscope. They appear as gaps, breaks, or unusual structures (Figs. 2 and 3) in a variable proportion of metaphases. The unusual chromosomal structures have arisen from breakage at the fragile site in a previous mitosis with the chromosomal material from either side of the fragile site ending up in different daughter cells.

Fragile sites are easier to see on plain-stained chromosomes than on banded chromosomes, especially when they occur in pale G-bands, as most do. It is often possible to see a fine strand of chromatin across the gap(s) at the fragile site.

The proportion of metaphases in which any particular fragile site is seen is highly variable. The common fragile sites, especially the aphidicolin-inducible ones are not often seen in more than 10% of metaphases but occasional individuals are

Tab. 4 Characterized group 4 common fragile sites.

Fragile site	*Approximate size*	*Gene content*
FRA2G	1 Mb	7 genes
FRA3B	900 kb	FHIT
FRA6F	1.2 Mb	5 genes
FRA7G	600 kb	CAV1, CAV2, TES, several more
FRA7H	160 kb	? none, contains SV40 integration site
FRA9E	9 Mb	PAPPA, at least 16 others
FRA16D	270 kb	WWOX1
FRAXB	500 kb	STS, GS1, TRL5A

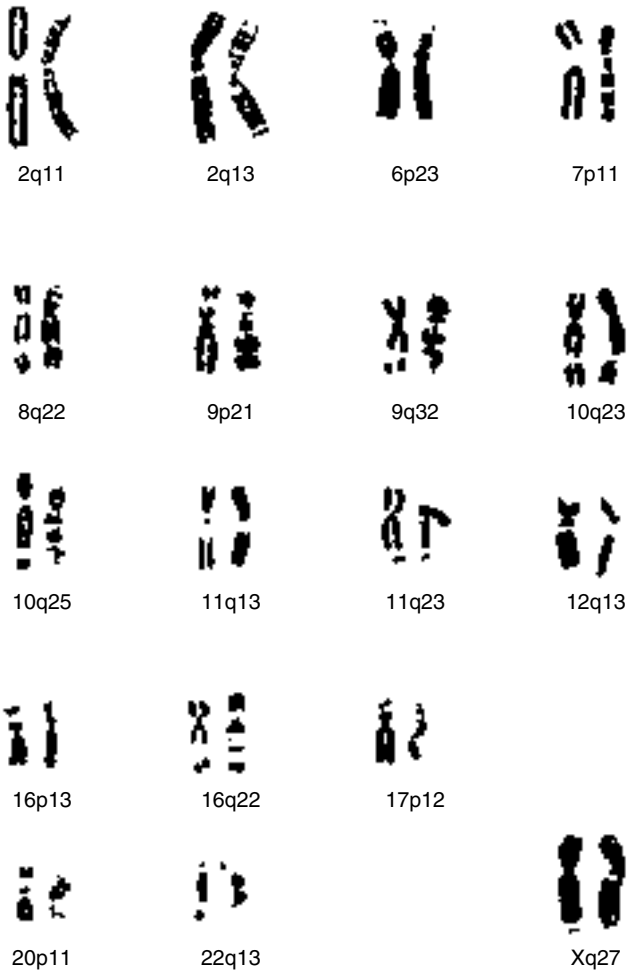

Fig. 2 A selection of rare fragile sites. The chromosome on the left of each pair is plain-stained and the one on the right is G-banded.

encountered in whom one of these may be present in up to 30% of metaphases. The common fragile sites can be seen on both members of a chromosome pair in a single cell (homozygous expression). The rare autosomal fragile sites have never been seen in homozygotes, except for *FRA10B*, *FRA16B*, and *FRA17A* where this is without apparent phenotypic effect.

The rare fragile sites are not often seen in more than 50% of metaphases and are more typically present in 20 to 30% although some obligate carriers of a fragile site (from family studies) will not express it at all (presumed premutation carriers, see Sect. 4). An exception to these levels of cytogenetic expression is *FRA16B*; when induced with berenil, it can often be seen in more than 90% of metaphases.

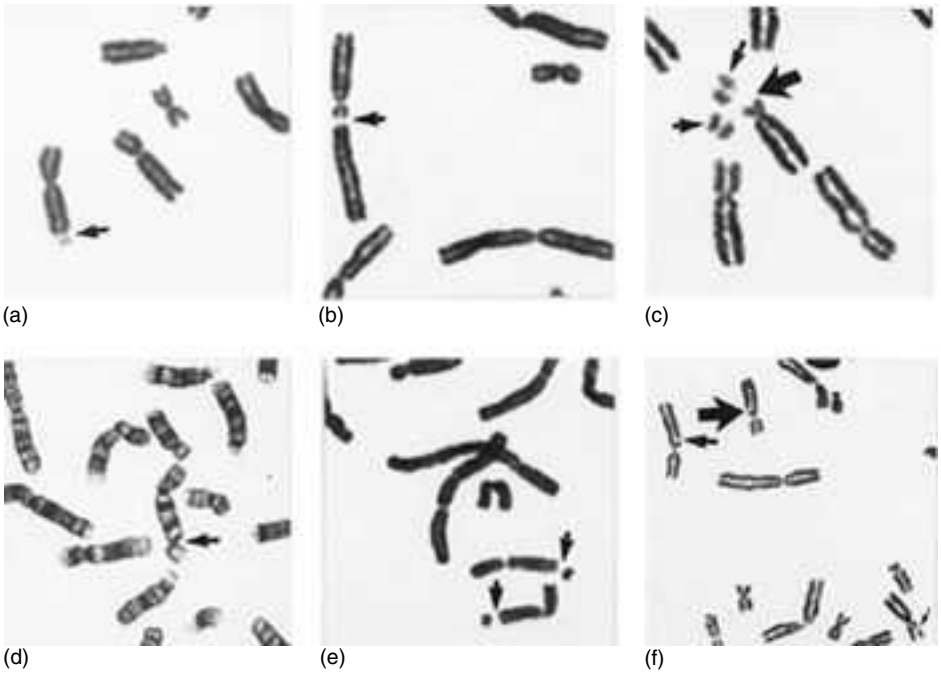

Fig. 3 Partial metaphases showing the appearance of various fragile sites (arrowed). 6
Induction of Fragile Sites

Fragile sites have primarily been studied in chromosomes prepared from phytohemagglutinin stimulated human lymphocyte cultures. While some fragile sites can be induced in chromosomes from fibroblast or lymphoblastoid cultures and somatic cell hybrids, such induction is more difficult and the fragile sites are usually seen in lower proportions of metaphases than in lymphocyte cultures. Since the conditions required for induction of fragile sites differ for each of the groups shown in Table 1, each will be considered separately.

6.1
Group 1

These fragile sites require a relative deficiency of dCTP or dTTP at the time of DNA synthesis. A deficiency of dTTP can be achieved by using tissue culture medium free of folic acid and thymidine, by adding an inhibitor of folate metabolism such as methotrexate, aminopterin or trimethoprim, or specific inhibitors of thymidylate synthase such as fluorodeoxyuridine. A high concentration of thymidine in the culture medium will lead to a deficiency of dCTP resulting in fragile site expression. Induction conditions need to be in place for at

least 24 h before chromosome preparations are made.

6.2 Group 2

All these fragile sites are induced by distamycin A and a number of related compounds that bind to the minor groove of the DNA molecule in AT-rich regions. The most effective of these compounds is berenil. The two fragile sites in subgroup (a) are distinguished from those in subgroup (b) by also being inducible with BrdU, although this is not as effective an inducing agent as berenil.

6.3 Group 3

The two fragile sites are induced only by BrdU and the related compound BrdC.

6.4 Group 4

This large group of common fragile sites is seen in a small proportion of metaphases under the conditions that induce the Group 1 fragile sites. They can also be specifically induced by aphidicolin. Aphidicolin is added 24 h before chromosome harvest, and the addition of caffeine for the last 6 h of this period boosts the proportion of metaphases in which the fragile sites are seen.

6.5 Group 5

These fragile sites are induced by 5-azacytidine, which is added 8 h before chromosome harvest. If the addition is much before or after this timing, the fragile sites are not seen.

6.6 Group 6

BrdU induces these fragile sites and again the timing of addition of the compound is important. Maximum induction occurs when the addition is 4 to 6 h before chromosome preparation. If the BrdU is present for 24 h or more, none of these fragile sites will be seen.

7 Inheritance

The patterns of inheritance of some fragile sites are very unusual. The common fragile sites have not been studied and since they are on all chromosomes, no abnormalities in their inheritance would be expected. Of the rare fragile sites, the fragile X (*FRAXA*) associated with fragile X syndrome has been most studied. Before the molecular characterization of this fragile site, the inheritance patterns were particularly puzzling. Normal Mendelian segregation ratios were not seen, the penetrance of the fragile site and its associated syndrome depended upon position in the family (this anomaly was known as the *Sherman paradox*) (Fig. 1) and the intellectual status of the mother. There were normal males who had transmitted the fragile X, and fragile X syndrome was only apparent when the abnormal chromosome was inherited from the mother.

These anomalies in fragile XA inheritance were explained by the molecular characterization of the fragile site. The chance of a premutation expanding to a full mutation in a child is a function of the size of the mother's premutation. Full mutations only rarely regress to premutations when transmitted by women, but inevitably do so when transmitted by men.

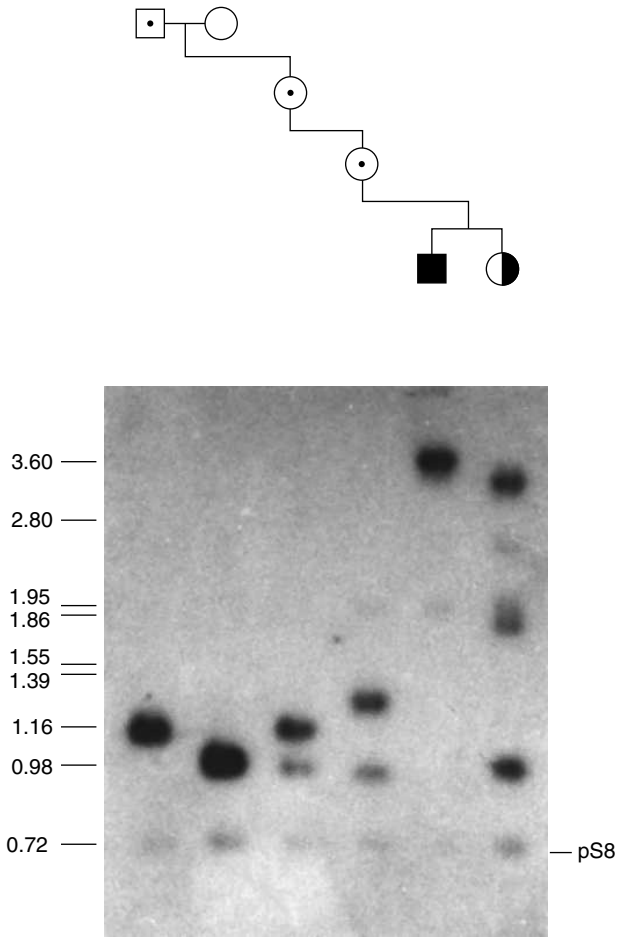

Fig. 4 Inheritance of the fragile X unstable element in a four-generation lineage from a large affected pedigree. Chromosomal DNA was digested with PstI and probed with pfxa3. Pedigree symbols: normal carrier male (dot in square); normal carrier female not expressing the fragile X (dot in circle); normal carrier female expressing the fragile X (half-shaded circle); affected fragile X syndrome male expressing the fragile X (shaded square); normal female (open circle). The carrier male in the first lane has no normal 1-kb band but a ~1.15 kb band, his wife in the second lane has a 1-kb band. The daughter in lane 3 has a ~1.15-kb band on her fragile X from her father and a 1-kb band from her mother. When this daughter has transmitted this band to her daughter, the fragile X band has increased to about 1.3-kb in size. This band has increased dramatically in size to about 3.5 kb in the fragile X syndrome boy, and appears as a somatically unstable smear in the carrier girl who expresses the fragile X (last lane). She has major bands of about 3.2-kb and 1.9-kb and a 1.0-kb band from her normal X chromosome.

Apart from the fragile sites on the X chromosome, there have been limited studies on the other Group 1 fragile sites. These are fully penetrant when transmitted by women but only 50% penetrant when transmitted by men. The reasons for this are unclear at this time. While the two autosomal Group 1 sites that have been cloned so far (*FRA16A* and *FRA11B*) have similar molecular mechanisms to the fragile X, very few family studies at the molecular level have been performed. While in at least the case of *FRA16A* and *FRAXE*, a male can transmit a full mutation, nothing is known about the likelihood of this happening.

The more frequently seen of the group 2 and 3 fragile sites (*FRA16B* and *FRA10B*) appear to have normal inheritance patterns.

8
Clinical Significance

8.1
The Fragile X Syndromes

One fragile site on the X chromosome (*FRAXA*) is of major medical significance in that it is a visible manifestation of the full mutation at this locus, which inactivates the *FMR1* gene. This gives rise to the *fragile X syndrome*, the most common familial form of intellectual handicap and one of the world's most common genetic diseases. This disease has been found in all population groups exposed to Western medicine but it is unknown whether it has the same frequency in all populations. Approximately 1 in every 4,000 children has fragile X syndrome.

Another fragile site on the X chromosome (*FRAXE*) is associated with a mild form of mental retardation. These males have no physical anomalies and the associated gene, *FMR2*, was the first to be isolated for nonspecific X-linked mental retardation. More than 50 families have been recorded in which mental retardation associated with this fragile site is present.

8.2
Other Fragile Sites

Some mothers of children with a mental retardation/malformation condition known as *Jacobsen syndrome* have *FRA11B*. Jacobsen syndrome is due to a deletion of part of the long arm of chromosome 11 and the deletion breakpoints in some cases are at or very close to the fragile site on their mother's chromosome. This is the only autosomal fragile site with possible clinical significance. Even here, very few women with *FRA11B* will have a child with Jacobsen syndrome and most Jacobsen syndrome patients have their chromosome 11 breakpoint distal to the fragile site.

The only rare autosomal fragile sites to have been recorded in homozygous form are *FRA10B*, *FRA16B*, and *FRA17A* where they are without apparent phenotypic effect. Group 1 autosomal fragile sites have never been seen in homozygotes. Any clinical effect in homozygotes would presumably depend upon the function of the gene in which the fragile site was located. It is likely that the presence of a fragile site detected cytogenetically means that a full mutation is present and any gene in which the fragile site is located is inactivated.

8.3
Cancer

There has been controversy for many years about a possible role for fragile sites in oncogenesis. The hypothesis is

that breakage at the fragile sites could give rise to chromosome rearrangements of the types seen in tumor tissue. Most studies had shown that when breaks in such rearrangements were carefully mapped in relation to fragile sites, the two did not coincide. However, *FRA11B* is within the oncogene *CLB2*, and a number of the common (group 4) fragile sites have within them putative tumor-suppressor genes. Nevertheless, there is no evidence that individuals with rare fragile sites (and everyone has all the common ones) are at any discernibly increased risk of developing malignant disease.

Keywords

Allele
Alternative form of a gene found at the same locus on homologous chromosomes.

CGG-repeat Expansion
Repeated-sequence CGG at the DNA level. When the number of repeats increases, this is referred to as an expansion.

FMR1
Gene that is shut down and causes fragile X mental retardation.

FMRP
The protein product of the *FMR1* gene.

Fragile Site
Can be induced in chromosomes by culturing cells in a folate-deficient medium.

Full Mutation
Is defined as a mutation in the *FMR1* gene with phenotypic symptoms.

Genotype
Genetic constitution of an individual.

Isoforms
Alternative splicing products of a gene.

Normal Transmitting Male
A phenotypically normal male who is a carrier of a premutation in the *FMR1* gene and may show cytogenetic expression of the fragile site.

Phenotypic
Observable characteristics.

Premutation
Is defined as a mutation in the *FMR1* gene without phenotypic symptoms.

Ribosome
A subcellular structure involved in protein production.

Fragile X syndrome is the most common form of inherited mental retardation. The disease is caused by methylation-induced transcriptional silencing of the fragile X mental retardation 1 gene (*FMR1*) as a result of the expansion of a CGG repeat in the 5′ UTR of the gene. This leads to the loss of fragile X mental retardation protein product (FMRP). FMRP is an RNA-binding protein that associates with translating polyribosomes as part of a large messenger ribonucleoprotein (mRNP) and modulates the translation of its RNA ligands. The *in vivo* targets of the FMRP are beginning to be elucidated and have been shown to include a subset of RNAs with a planar structure called *G-quartet*.

To study the physiological role of the FMR1 protein, animal models have been developed, including genetically modified mouse and *Drosophila*. The loss-of-function mouse model shows some features comparable to human patients including enlarged testes, a subtle behavioral phenotype, and discrete anomalies of dendritic spines. Studies in *Drosophila* indicate that dFmr1 in flies plays an important role in synaptogenesis and axonal arborization, which may underlie the observed deficits in flight ability and circadian rhythm in the dFmr1-mutant flies.

1 Introduction

Mental retardation can be defined as a failure to develop cognitive abilities and achieve a level of intelligence that would be appropriate for the age group. A percentage of the general population, variably estimated between 0.5 and 3%, is reported to be functioning two standard deviations below the average (i.e. to have an IQ of less than 70). Genetic determinants underlie approximately half of these conditions and an excess of affected males has often been reported, especially in the mild-to-moderate mental retardation range with an IQ between 70 and 35. Excess of males with mental retardation compared to females was eventually interpreted as being due to X-linked factors. One of the first described X-linked heritable mental retardation syndromes is the fragile X or Martin–Bell syndrome. After trisomy 21 or Down syndrome, it is the most frequent cause of mental retardation.

2 Description of Fragile X Syndrome

2.1 Some Historical Aspects

In 1943, Martin and Bell reported a large family in which 11 mentally retarded boys were born to mothers of normal intelligence and hypothesized that the mental defect of the boys was due to a sex-linked recessive gene, which was suppressed in the two grandfathers. More than a quarter of a century later, Lubs reported a unique cytogenetic marker at the end of the long arm of the X chromosome (Xq27.3) in cultured lymphocyte cells from four retarded male patients in a family with X-linked mental retardation. As more pedigrees were identified in which the marker on the X chromosome segregated with mental retardation, it became clear that the fragile site could be used as a diagnostic tool. In 1978, Turner observed macroorchidism (enlarged testicles) in a

large proportion of the patients with the fragile site. Reinvestigation of the pedigree described by Martin and Bell revealed a fragile site and the typical features of the syndrome in the affected patients. In recognition of the first published pedigree, the mental retardation syndrome associated with the fragile site on the X chromosome and macroorchidism was named *Martin–Bell syndrome*, though these days it is more usually called *fragile X syndrome*.

2.2 Fragile Site

Before the cloning of the responsible gene in 1991, the laboratory confirmation of the diagnosis of fragile X syndrome was dependent on cytogenetic detection of the fragile site at Xq27.3 in cultured lymphocytes, fibroblasts, or amniocytes (Fig. 1). This fragile site was called FRAXA (fragile site, X chromosome, A site), as it was the first fragile site identified on the X chromosome. On metaphase spreads, fragile sites are microscopically visible as a gap or a break. The fragile site is induced by culturing cells under folic acid deprivation before chromosome spreads are made. The percentage of cells that show fragile site expression may vary from individual to individual, a phenomenon for which there is no explanation. In fragile X males, the fragile site is usually seen in 2 to 60% of the cells, but the site can only be detected in 50% of obligate carrier females, limiting the utility of cytogenetic carrier detection in pedigrees.

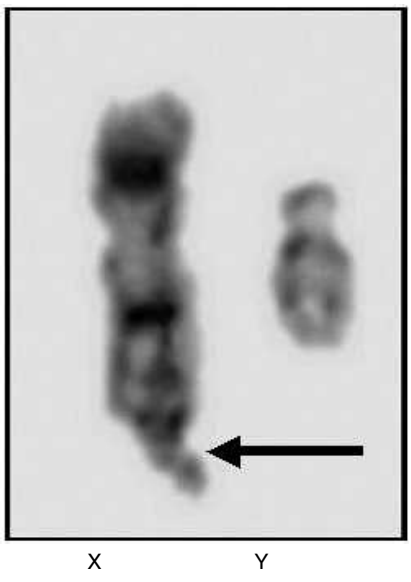

Fig. 1 Cytogenetic expression of the fragile site at Xq27.3 in a patient is clearly visible and indicated with an arrow.

2.3 Unusual Pattern of Inheritance

From the initial observations onward, it was clear that fragile X syndrome has an unusual pattern of inheritance (Fig. 2). In X-linked recessive diseases, female carriers are usually unaffected and transmit their carrier status to half of their daughters, while half of their sons may develop the disease. However, in the case of the fragile X syndrome, 30% of carrier females are mentally retarded, although often less severely than males. In addition, 20% of males with cytogenetic expression of the fragile site are not affected. Such males, called *normal transmitting males* (NTMs), pass the mutation on to their unaffected daughters. However, these carrier daughters have a 40% risk of transmitting the disorder to their sons. In comparison, sons of affected females have a recurrence risk of 50%. Only transmission through the female line can give rise to a full phenotype in the next generation. Other peculiarities include the

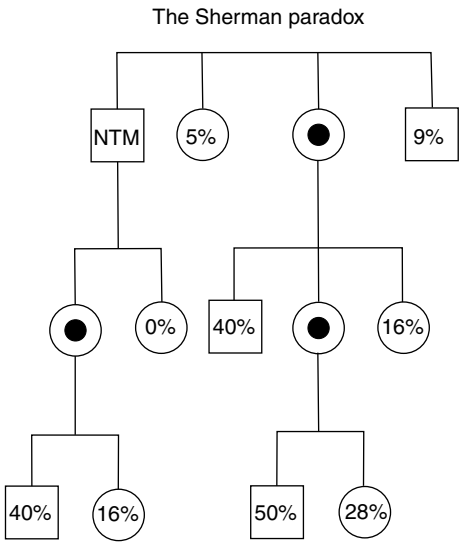

Fig. 2 A schematic representation of a fragile X family illustrates the Sherman paradox. The position within the pedigree affects the chance (indicated as a percentage) of being affected with the fragile X syndrome. NTM, normal transmitting male.

observation that more patients occur in the youngest generation of the pedigree. This increase in the penetrance of the disease with generations is called the *Sherman paradox*. The abnormal inheritance pattern could only be explained after the cloning of the gene and elucidation of the peculiar mutational mechanism.

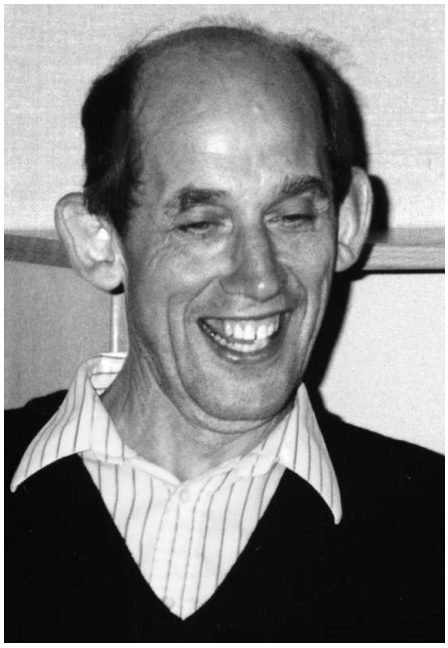

Fig. 3 Male fragile X patient displaying the typical facial characteristics of the syndrome with a long face and prominent ears.

2.4 Phenotype

Fragile X syndrome has an incidence of about 1 in 4000 males and 1 in 6000 females. Males suffer from mild to severe mental retardation with an IQ between 20 and 60, while females are usually less severely affected. Macroorchidism develops during or after puberty and is seen in more than 80% of all adult patients. Fragile X patients show physical characteristics such as a typical long face and prominent ears (Fig. 3), but these symptoms can be absent in younger children. Hyperextensible joints, hand calluses, and flat feet can also be observed and may point to connective tissue dysplasia. Associated behavioral problems may include hyperactivity, decreased attention span, repetitive behavior, poor eye contact, tactile defensiveness, and shyness. Speech and language skills are usually impaired in older boys. In 13 to 23% of the male patients, autistiform features have been observed, occurring mostly before adulthood. Notwithstanding this observation in a proportion of fragile X patients, there seems to be no general

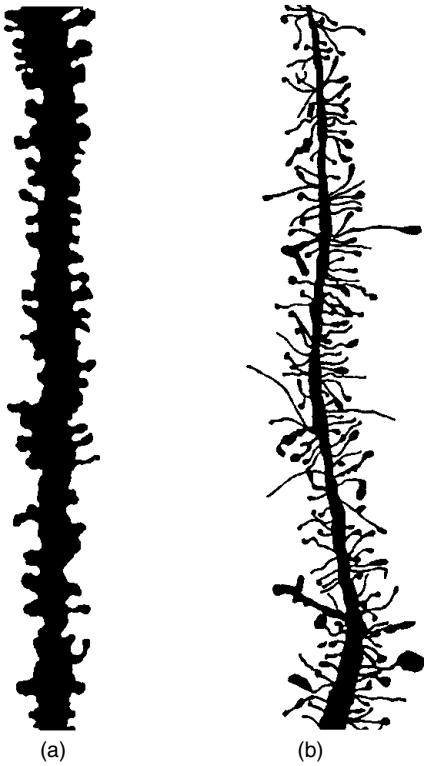

Fig. 4 Example of a typical spine morphology on dendrites from (a) a fragile X syndrome patient and (b) an unaffected control. Dendrites of the fragile X patient display more immature spines and a higher spine density. (Reprinted with permission from Fiala et al. (2002).)

association between fragile X syndrome and autism. In addition, fragile X boys suffer from a greater variability in total sleep time and sleep-rhythm maintenance when compared to controls. Fragile X patients have a normal life span.

2.5 Neuroanatomy

Brain abnormalities in fragile X patients have been determined using magnetic resonance imaging (NMR). A reduction in the size of the posterior cerebellar vermis and enlargement of the fourth ventricle compared to controls was reported. An increased volume of the hippocampus and the lateral ventricles in fragile X males was observed together with a significantly larger volume of the caudate nucleus. This is an important observation since the caudate nucleus, together with the lenticular and thalamic nucleus, forms the subcortical gray that allows the cerebral cortex to have an influence on behavior. In 3D reconstructions, fragile X brains appear to be larger than control brains. Volumetric changes were not confirmed by physical measurement of the brains of two deceased fragile X patients in a separate study.

An impaired neuronal development has been observed in fragile X patients. The spines on apical dendrites of pyramidal cells in the Golgi-impregnated visual and temporal cortex of fragile X patients are long, tortuous, immature, and thin, and fragile X patients exhibit an increased spine density on distal segments of apical dendrite shafts (Fig. 4). The higher spine density contrasts with other known mental retardation syndromes such as Down syndrome, in which a lower spine density is observed.

3 Identification of the Causative Gene

3.1 The Cloning of the Gene

Initially, the genetic defect underlying the fragile X syndrome was unknown and diagnosis was only based upon the observation of the fragile site at Xq27.3 in cultured cells. Positional cloning enabled

the isolation of the gene and helped understand the molecular mechanism leading to the disorder. Linkage analysis with polymorphic markers placed the fragile X locus between factor IX at Xq27.1 and factor VIII at Xq28, conforming the locus for the gene at or nearby the fragile site. Hybrid cell lines with translocation break points at the fragile site were very useful in developing and mapping new probes near the gene. Two cell lines, termed Micro21D and QIX, each containing a reciprocal part of the human X chromosome, were especially helpful. Micro21D contained the Xpter–Xq27.3 part of the human X chromosome and Q1X contains the Xq27.3–Xqter part of the human X chromosome.

Using markers linked to the fragile site, several YACs ranging from 200 to 950 kb could be isolated. Among these, YAC 209G4 contained 475 kb human DNA and was shown to cross the fragile site by *in situ* hybridization. A cDNA clone was isolated from a human fetal brain library using cosmids from this particular YAC and this gene was assigned the name *FMR1* (Fragile X Mental Retardation 1). Further analysis of this gene sequence showed that the translation breakpoints of Micro21D and Q1X lie in exon 1 of the gene. Surprisingly, exon 1 contained a trinucleotide repeat that shows length variation between control and fragile X patients. Expansion of the CGG repeat was shown to be involved in both the inactivation of the *FMR1* gene and the cytogenetic expression of the fragile site.

3.2 Dynamic Mutation

Studying the dynamic inheritance pattern of the CGG repeat resolved the complex inheritance of the fragile X syndrome. In more than 99% of all fragile X patients, the syndrome is caused by a dynamic expansion of a CGG repeat in the 5′ untranslated region (5′UTR) of the *FMR1* gene (Fig. 5). In the normal population, the CGG repeat is polymorphic with allele sizes between 5 and 50 repeat units, 30 units being the most frequent allele size. Alleles of this size range are inherited stably from generation to generation and the gene is transcribed and translated into protein. In patients, a trinucleotide CGG expansion of more than 200 to several thousands of CGG repeats, referred to as a *full mutation*, is observed. Because of the repeat expansion, the CGG repeat and the surrounding promoter region of the *FMR1* gene is methylated, inhibiting mRNA translation and causing absence of the protein product. Absence of the FMR1 protein product, FMRP, causes the characteristic features of the fragile X syndrome. The alleles with a repeat size between 50 and 200 CGG units are called *premutation alleles*. Premutations are unmethylated and produce FMR1 mRNA and FMRP. Premutation carriers are not affected with fragile X syndrome. However, repeats in the premutation size range may be instable upon transmission to the next generation. Expansion to a full mutation occurs only through maternal transmission, explaining why only progeny of female premutation carriers is at risk for the fragile X syndrome. The observation that the larger the premutation, the more likely it will expand to a full mutation in the next generation, resolved the Sherman paradox.

The number of CGG repeats itself does not always allow discrimination between the three categories of repeat sizes. Repeats of 200 to 230 CGG units can be either large premutations or small full mutations. However, discrimination between the two types of mutations is possible on

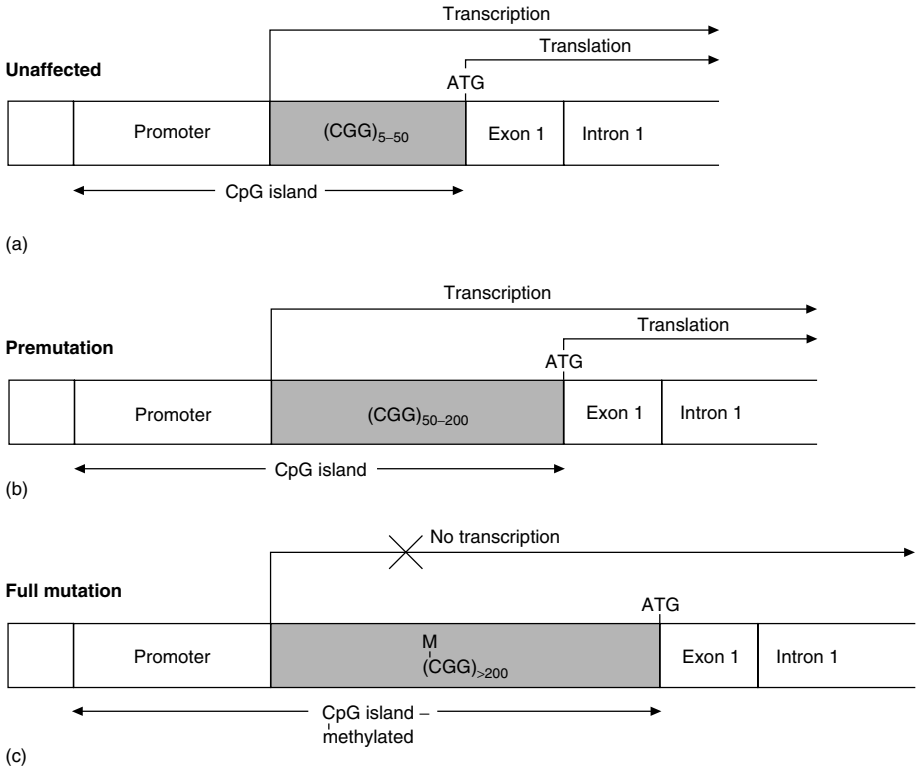

Fig. 5 Schematic representation of the transcription of (a) the *FMR1* gene in normal controls, (b) premutation carriers, and (c) full-mutation patients. The normal and the premutation size alleles (a and b) are transcribed and translated into FMRP. The full-mutation allele (c) is hypermethylated and therefore not transcribed.

the basis of the methylation status. Alleles comprising 45 to 60 CGG units are referred to as being of intermediate size. These may inherit stably, but may also increase or decrease by a few CGG units in length during transmission and become premutation alleles at risk for expansion to a full mutation in future generations. Factors influencing repeat stability include, but are limited to, the amount of AGG interspersions in the CGG repeat. In the *FMR1* gene, on average every 10th CGG repeat unit is interspersed with an AGG triplet. AGG repeats stabilize the repeat; fewer the AGG interspersions, the more prone it would be to intergenerational expansion. The instability threshold for FMR1 alleles is estimated to be about 34 to 38 uninterrupted CGG repeats, and the expansion of an interrupted CGG repeat of 59 units to a full mutation in the next generation has been observed.

4 *FMR1* Gene and Protein

4.1 Gene Structure and Expression Pattern

The *FMR1* gene has a genomic size of approximately 38 kb and consists of

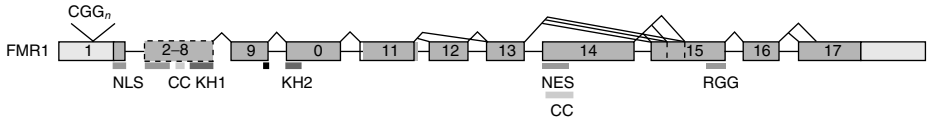

Fig. 6 The *FMR1* gene containing 17 exons and a CGG repeat in the 5′ UTR. The splice sites as well as the positions of the functional domains are indicated. NLS, nuclear localization signal; NES, nuclear export signal; CC, coiled coils; KH/RGG, KH, and RGG domains are important for RNA binding.

17 exons (Fig. 6). The transcript length is 4.4 kb, and all elements necessary for proper FMR1 expression *in vivo* are present in a 2.8 kb fragment immediately upstream of the ATG. The promoter sequence is GC-rich, as found in many housekeeping genes. Footprinting analyses of the promoter site revealed consensus-binding sites for ubiquitously expressed transcription factors such as Sp1, H4TF1/Sp1-like, and c-myc. In addition, an AP-2 binding site, specific for neuronal expression, was identified. Upstream of the CGG triplet repeat, a 20-nucleotide-long internal ribosome entry site (IRES) was identified. The function of this element in FMR1 is unclear, but IRES elements of other mRNAs play a role in neuronal regulation of translation in response to synaptic stimuli.

By Western blotting using antibodies directed against FMRP, different isoforms were identified with a molecular mass around 70 to 80 kDa and a maximal protein length of 631 amino acids. Excessive alternative splicing occurs especially in the 3′ terminal half of the gene, in exons 12, 14, 15, and 17 (Fig. 6). This can potentially give rise to 12 different mRNAs and protein isoforms. Skipping of exon 14 introduces a frameshift in the open reading frame, resulting in a different amino acid order in the carboxyl terminal half of the protein. The function of the different isoforms is still unknown and the different splice products are not tissue-specific. FMRP shows near-ubiquitous expression. It is highly expressed in ovary, thymus, eye, spleen, and esophageal epithelium with an abundant expression in brain and testis and a moderate expression in colon, uterus, thyroid, and liver, and little or no expression in the heart, aorta. or muscle. In the brain, the FMRP expression is restricted to differentiated neurons and Purkinje cells and is absent in nonneuronal cells. Neuronal FMRP is concentrated in the perikaryon and proximal dendrites and is also expressed in the synapses but is not detected in the axons. Especially high expression was found in Purkinje cells of the cerebellum and in neurons of the granular layer, the cortex, and the hippocampus. In the testis, the FMRP is expressed in the cytoplasm of primordial germ cells and in the early spermatogonia adjacent to the basal membrane of the tubuli seminiferi. Immunocytochemical studies revealed that FMRP is predominantly localized in the cytoplasm with high levels found near the rough endoplasmic reticulum, but some nuclear expression was also observed by both light and electron microscopy.

4.2 Structural Domains of FMRP

Two types of RNA binding domains have been identified in the protein, including two KH domains that show homology

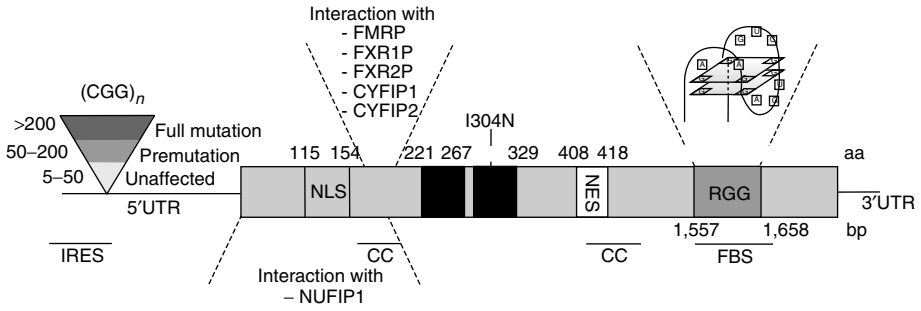

Fig. 7 Schematic representation of the FMR1 mRNA and protein. The known domains are indicated: IRES, internal ribosome entry site; NLS, nuclear localization signal; CC, coiled coils; KH, K-protein homology domain; NES, nuclear export signal; RGG box, Arg-Gly-Gly triplet; FBS, FMRP binding site. In addition, the Ile304Asn missense mutation found in a single, most severely affected patient is indicated. In the 5′ UTR, the different repeat classes are represented. The G-quartet structure present in the mRNA is depicted above FBS that overlaps with the RGG box. The interacting regions of FMRP with its paralog genes, *FXR1* and *FXR2*, and with other identified proteins, CYFIP proteins and NUFIP1, are indicated.

to hnRNP K domains and an RGG box containing a conserved Arg-Gly-Gly triplet. In addition, a nuclear localization signal (NLS), a nuclear export signal (NES), two coiled coils, and a G-quartet-binding structure have been identified (Fig. 7).

The KH domain consists of the consensus sequence, I/L/V-I-G-X_2-G-X_2-I. It is usually present in more copies in a protein and is able to bind ssRNA, mRNA, and rRNA. Using NMR (nuclear magnetic resonance), the KH domain was shown to consist of a stable three-stranded antiparallel β-sheet, orientated against three α-helices. The $\beta\alpha\alpha\beta\beta\alpha$ folds to a surface for RNA binding and a conserved Gly-Lys-X-Gly is centered on the loop between the first two helices. The importance of the KH domain for proper FMRP function is illustrated by a rare, unique patient with an Ile304Asn mutation located in the second KH domain. The mutated isoleucine is highly conserved in the KH domain sequence. The patient has a phenotype much more severe than any other known fragile X patient, including profound mental retardation and excessive macroorchidism. This patient still generates FMRP. The mutant FMRP has impaired RNA-binding capacity under elevated salt conditions. The mutation disrupts the normal folding of the KH domain. The FMRP–RNA binding can be disrupted by deletion of the C-terminus of the protein, containing the RGG box, suggesting that the RGG box plays an important role in FMRP–RNA binding. The RGG coding region of the FMR1 protein shows a high affinity for its own mRNA and other G-quartet-containing mRNAs, further described in Chapter 3.5. All these findings let us assume that FMRP has multiple binding regions to associate with RNA. *In vitro* translated FMRP binds directly to RNA homopolymers. It shows highest affinity for poly(G), a lower affinity for poly(U), and no affinity for poly(A) or poly(C). FMRP is able to bind selectively 4% of all brain mRNAs including its own mRNA, confirming that FMRP is an RNA binding protein. The creation of deletion mutants of FMRP, missing the N-terminal, the C-terminal, or

one of the KH domains, revealed that only the first KH domain interacts with RNA. This result agrees with the findings that the Ile304Asn mutant is still able to bind some RNAs since the mutation is situated in the second KH domain, although the capacity to bind poly(U) homopolymers is destroyed. Both the N-terminal and the C-terminal show RNA-binding abilities and the N-terminal binds poly(G) with a similar preference as the first KH domain.

FMRP contains both an NES and an NLS signal. The NES is approximately 10 amino acids long and resembles the NES motif of HIV1 Rev. It consists of a small stretch of hydrophilic amino acids containing four critically spaced, large, hydrophobic amino acids. The NES is located in exon 14 and absence of this exon results in trapping of the FMRP in the nucleus. The nuclear export mediated by the NES of FMRP is exportin1-dependent, since Leptomycin B treatment, an antibiotic acting specifically on exportin1, causes the accumulation of FMRP in the nucleoplasm. The NLS contains clusters of basic amino acids, but the sequence does not resemble other known nuclear localization signals. It is located between residues 115 and 154. The nuclear localization of FMRP mediated by the NLS is an energy-dependent process. The presence of both an NES and an NLS may suggest that the fragile X protein shuttles through the cell into and out of the nucleus. In accordance with this hypothesis, the protein has been observed in the nuclear pore during transfer between the nucleus and the cytoplasm.

FMRP contains two coiled coils involved in protein–protein interaction and located in exon 7 and in exons 11 to 14 respectively. The first coiled coil is potentially involved in binding of FMRP interacting proteins, while the second was suggested to play a role in FMRP–ribosome binding.

4.3 FMRP Associates with Ribosomes as Part of an mRNP

In human cell lines, FMRP colocalizes primarily with polyribosomes and rough endoplasmic reticulum. High levels of FMRP were found in perikarya, where it is concentrated in regions rich in ribosomes, particularly near or between rough endoplasmic reticulum cisternae. FMRP has also been detected in the granular component of nucleoli in COS cells. The nucleolus is a cellular component formed in response to the requirement for new ribosome synthesis. The FMRP–ribosome association is sensitive to 500 mM salt concentration and to low concentrations of RNase digestion that does not disturb the ribosome assembly *per se*. This suggests that FMRP is bound to the ribosomes via RNA. These findings are in contradiction with earlier experiments that suggested that FMRP binds to the 60S ribosomal subunit via part of exon 13 and 14, containing the second coiled coil domain. Whatever the role of the FMRP–60S ribosome binding, the RNA–protein interaction seems the most important as nearly all cytoplasmic FMRP can be cocaptured with poly(A) mRNA. Moreover, after EDTA treatment, the FMRP complex is released from the ribosomes.

In the cell, FMRP forms a messenger ribonucleoparticle, mRNP, with a sedimentation value of 60S and a size >660 kDa. The composition of the mRNP complex is not known, but some proteins involved in the mRNP particle include FXR1 and FXR2, paralogs of FMR1 (Chapter 4), NUFIP and CYFIP proteins (Chapter 5), nucleolin, a known protein in other mRNPs,

and an ortholog of the mouse protein 1/p50. It is not known whether all mRNP particles containing FMRP have the same composition. If this is not the case, the absence of FMRP may influence the functioning of the different types of mRNPs in a different way.

4.4 FMRP as a Possible Inhibitor of Translation

The association of FMRP with the polyribosomes suggested a potential controlling role in mRNA translation and stability. *In vitro*, FMRP is able to suppress translation of mRNA. This inhibition is dosage-dependent and is observed for all mRNAs tested at low FMRP concentrations in an *in vitro* synthesis system and in microinjected *Xenopus laevis* oocytes. This may suggest that cells with absent FMRP translate certain mRNAs in excess. Nevertheless, a study by Brown et al. (2001) (Chapter 3.6) showed that increased and decreased amounts of specific polysome-bounded mRNAs occur in fragile X patients. It was suggested that elevated levels of FMRP are sequestering mRNAs into incompetent granules causing the repression of reporter genes. Recently, it was reported that only a minor fraction of newly synthesized FMRP is associated with polyribosomes, while the majority of it is found in cytoplasmic granules that are resistant to nonionic detergents. Increasing the amount of FMRP resulted in trapping of the mRNAs in these granules together with several other mRNA-binding proteins. This suggested a potential dual role for FMRP both as a transporter of specific mRNAs and also as a repressor of translation in specific conditions.

FMRP containing the Ile304Asn mutation fails to repress translation despite the fact that the RNA-binding capacity of mutated FMRP is only mildly affected. The mutated protein appears as a part of a smaller, abnormal mRNP that is not associated with translating polyribosomes, perhaps because FMRP is also able to form dimers but the Ile304Asn protein fails to do so. This suggests that the loss of association to ribosomes and to form normal mRNP particles causes the severe phenotype of this patient.

4.5 mRNA Targets of FMRP

As FMRP has RNA-binding capacities, identifying the mRNAs bound by FMRP in the cell is a prerequisite for understanding its function. An interaction of FMRP with the 3′ UTR of the myelin basic protein mRNA was found using purified recombinant FMRP. Using a biotinylated-FMRP affinity resign, Sung et al. (2000) identified nine mRNAs from adult brain that are able to bind FMRP, including a neuronal NT2 EST and Tip60a, a Tat interactive protein. Also the *Xenopus* elongation factor 1A, xEF-1A, binds strongly to human FMRP. FMRP was demonstrated to inhibit mRNA translation of this gene, and in the absence of FMRP, the translation of human EF-1A is derepressed.

Recently, the C-terminal region of FMRP was identified as major site of specific mRNA interaction. A specific, high-affinity binding site for its own mRNA in the RGG box region of FMRP was identified. A 100-nucleotide mRNA fragment, situated in the region encoding the RGG box, was shown to contain a purine-quartet motif predicted to form a planar structure. This so-called G-quartet structure was shown to be involved in the binding of FMR1-mRNA by FMRP (Fig. 7). At the same time, Darnell et al. (2001) identified FMRP-bound mRNAs, by screening a

pool of 96-mer RNAs containing 52 bases of random sequence. A common motif preferentially bound by FMRP was identified as a G-quartet.

In vivo studies also revealed G-quartet-containing mRNAs as targets of FMRP. mRNAs associated with FMRP-mRNPs that interact with active translating ribosomes in mouse brain were isolated and hybridized on microarrays containing a significant proportion of murine genes. By subtracting the expression patterns of knockout and control mice, RNAs specifically bound to FMRP were identified. In a similar way, mRNA populations in the polyribosomal fractions of lymphoblasts of fragile X patients were compared with controls. The studies revealed a long list of FMRP-associated mRNAs. A total of 426 mRNAs were identified in both the human and the mouse studies. Moreover, 14 of the mRNAs were identified in both the experiments of Darnell et al. (2001) and Brown et al. (2001). Eight of them revealed a G-quartet structure including, for example, NAP22, which is present in axon terminals and dendritic spines and plays a role in maturation or maintenance of synapses. In addition, in both studies MAP1B was identified, which is involved in transport within neurons and is the human ortholog of the *Drosophila* futsch gene (Chapter 6).

Using the Fmr1 knockout mouse model, Zalfa et al. (2003) revealed that FMRP regulates translation of specific dendritic mRNAs. The translational efficiency, the percent of a given mRNA that is associated with polysomes (PMP = Percent of Messenger on Polysomes), was quantified and shown to be different for specific RNAs, including those that encode for cytoskeletal proteins such as Arc and MAP1B and signal transduction molecules such as α-CaMKII. Interestingly, interaction occurred through a ribonucleoprotein complex that includes the small dendritic noncoding RNA BC1. It was shown that BC1 directly binds to FMRP and is able to base-pair with regions of complementarity between BC1 and the regulated mRNAs. BC1 may be required for FMRP association with the targeted mRNAs and for determining the binding specificity.

In vivo binding of mRNAs to FMRP in hippocampal neurons was determined using antibody-positioned RNA amplification, a novel technique that allows identification of RNAs that are directly associated with FMRP in the cell. Approximately 83 genes believed to interact directly with FMRP were identified. The FMRP interacting mRNAs were mostly involved in diverse aspects of synaptic plasticity and neuronal maturation. G-quartets are present in a small percentage of the mRNAs indicating that other factors in addition to the G-quartet are important in FMRP–RNA binding. Interestingly, some of the proteins encoded by the RNA showed a discrete change in abundance and subcellular distribution. The identified mRNAs include the glucocorticoid receptor α (GRα). It is a low-affinity receptor for corticosteroid hormones, involved in the electrical activity in the hippocampus in response to mineralocorticoid receptor stimulation. The receptor showed a change in dendritical distribution in the hippocampus of the knockout mouse. Diminished responsiveness of the receptor is compatible with learning problems observed in fragile X patients.

4.6 Function of FMRP in Neurons

The ability of FMRP to bind RNA, its association with ribosomes, and the observation that the protein shuttles through the cell lead to the hypothesis that

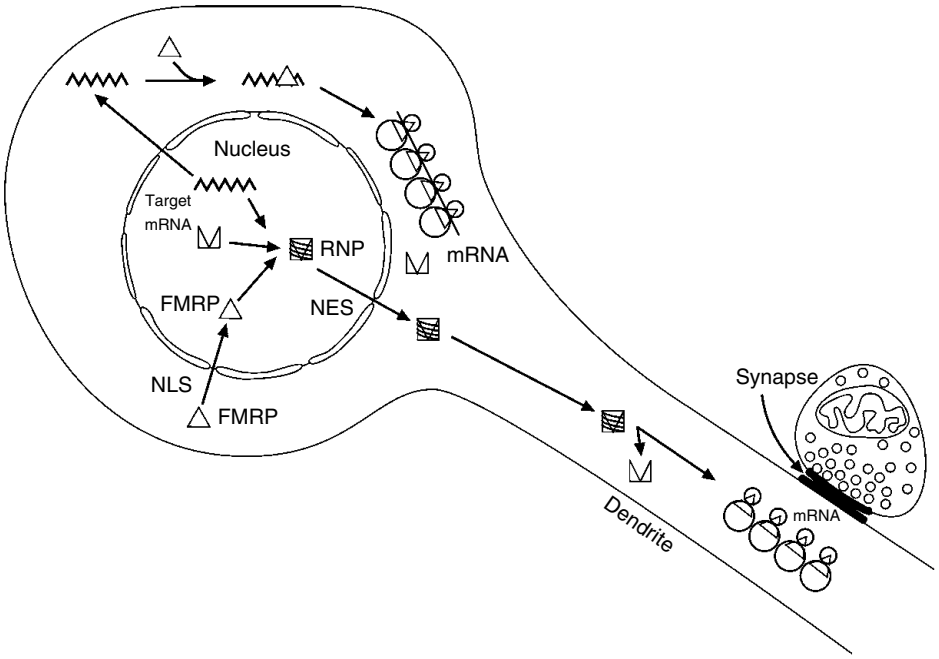

Fig. 8 A hypothetical model of the FMRP function in the neuron. FMRP is transported from the cytoplasm to the nucleus, where it assembles into an mRNP particle, containing specific mRNAs and other proteins. The mRNP particle is transported to the cytoplasm and mRNAs are presented to the polyribosomes in the perikaryon and the dendrites nearby the synapses.

FMRP may play a role in mRNA transport from the nucleus to specific destinations in the cell (Fig. 8). This hypothesis is supported by the observation that FMRP associates in the nucleus with mRNAs and proteins to form an mRNP particle that is transported through the cytoplasm and is presented to the ribosomes for translation. It is not clear what happens with FMRP after translation. FMRP may be released from the ribosomes as a free protein after translation termination or may be trapped in cytoplasmic granules.

Because of the putative role of FMRP in cellular mRNA transport, dendritic mRNA transport was investigated in an FMR1–EGFP stable transfected PC12 cell line with an inducible expression system (Tet-On) for regulated expression of the FMRP–GFP fusion protein. After Dox-induction, FMRP–GFP was localized in granules in the neurites of PC12 cells. Using time-lapse microscopy, the trafficking of FMRP–GFP granules into the neurites of living PC12 cells was demonstrated. Motile FMRP–GFP granules displayed two types of movements: oscillatory (bidirectional) and unidirectional anterograde. The average velocity of the granules was $0.19\ \mu m\ s^{-1}$ with a maximum speed of $0.71\ \mu m\ s^{-1}$. The movement of FMRP-labeled granules was microtubule-dependent. Colocalization studies showed that the FMRP–GFP granules also contained RNA, ribosomal subunits, kinesin heavy chain, and

FXR1P molecules as constituents. This observation stresses the putative role for FMRP–mRNP particles in dendritic mRNA transport to the synapse.

In the synapse, FMRP might regulate the translation of certain mRNAs. Interestingly, local protein synthesis plays an important role in neuronal processes, including learning and memory. FMRP can be detected in polysomes of synaptoneurosomes, neuronal preparations highly enriched in synapses. Synaptoneurosomes respond to stimulation by metabotropic glutamate agonists with fast-increasing polyribosome formation and accelerated protein synthesis. The synthesis of FMRP in the synaptoneurosomes increases after stimulation with the neurotransmitter glutamate, suggesting that synthesis of this protein in synaptoneurosomes is triggered by a class I glutamate receptor. On the other hand, different experiments reported that Fmr1 knockout mice have lowered expression levels of the glutamate receptor mGluR1 in the cerebral cortex and in the granule cell layer of the cerebellum, but not in the hippocampus. Thus, it has been suggested that this receptor alteration disturbs local protein synthesis and leads to impaired cortical synaptic plasticity. These findings suggest a specific function in the modulation of FMRP synthesis at postsynaptic sites and, in addition, that FMRP has a role in neurotransmitter-actuated polyribosome assembly. FMRP synthesis can also be affected by the brain-derived neurotrophic factor, BDNF, a known regulator of synaptic plasticity. BDNF downregulates the FMRP expression in cultured hippocampal neurons as well as in mouse brains. This downregulation by BDNF is a response to increased tyrosine kinase receptor signaling. The decreased FMR1-mRNA amounts could be correlated to a decreased amount of FMRP in the cell.

The *in vivo* trigger of FMRP synthesis is not known, but FMRP increases in the barrel cortex after whisker stimulation in rats, a model of experience-dependent plasticity. This increase was notably observed in subcellular fractions enriched for synaptoneurosomes and polyribosomes, suggesting a site-specific production of the protein. The altered level of FMRP most likely influences the translation of specific mRNAs in the synapse. Inhibition of the synthesis of its own mRNA, MAP1B, Arc, and α-CaMKII has been demonstrated, but it remains unclear whether all cellular RNAs that are bound by FMRP are translationally repressed.

Thus, FMRP plays an important role in translation of proteins in the dendrites after specific triggering. Abnormal synaptic protein synthesis in the absence of FMRP could underlie variable symptoms of the fragile X syndrome, including the presence of immature spines and impaired synaptic maturation.

5
Paralog Genes FXR1 and FXR2

FMR1 has two paralog genes called *FXR1* and *FXR2* (fragile X–related protein 1 and protein 2). FXR1 was identified by cross-hybridization with an FMR1 probe, while FXR2 was identified by yeast two-hybrid assays using whole FMRP as bait. The *FXR1* and *FXR2* genes have been localized to 3q28 and to 17p13.1 respectively. Overall similarity with FMR1 is high, especially in the amino-terminal half of the gene, and both FXR1 and FXR2 proteins contain identical functional domains as FMRP, including two KH domains, an RGG box, an NES, and an NLS (Fig. 9). Sequences

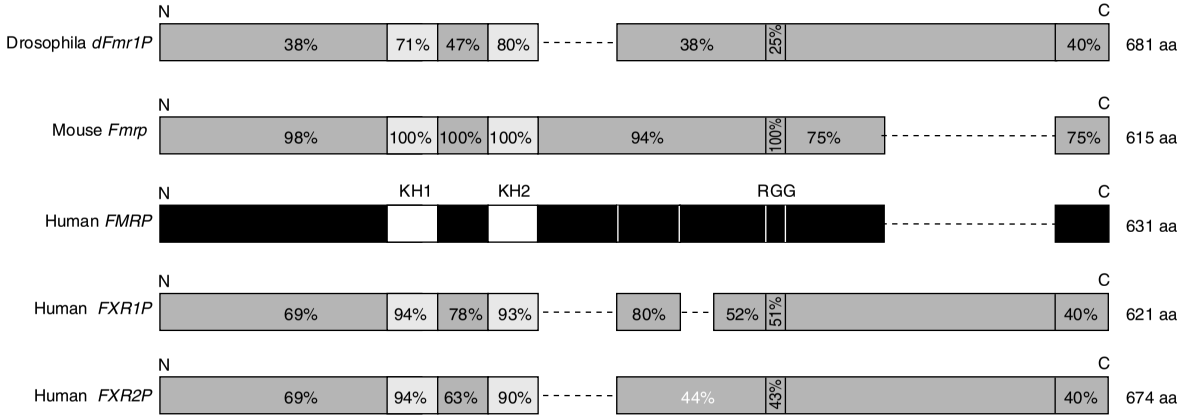

Fig. 9 Protein identity between human FMRP and human FXR1P and FXR2P, mouse Fmrp and Drosophila dFmr1P based on the alignment of Wan et al. (2000). The three RNA binding domains in the mouse Fmrp show 100% identity with the FMRP domains, whereas in the other proteins high identity is present in the KH domains and moderate identity in the RGG box region. Identity in the carboxyl end is not indicated because the low homology of the protein in this region does not allow an unambiguous alignment.

corresponding to exons 11 and 12 in FMRP are not identified in the two paralog genes. FMRP shows 86% and 70% homology to FXR1P and FXR2P respectively. Specific differences include the carboxyl end of FXR1P that is very different from that of FMRP and the FXR2P amino-terminus that contains an extra 10 amino acids compared to FXR1P and FMRP. The 5′ and 3′ UTR of FXR1 and FXR2 are up to five times shorter than that of FMR1. The 3′ UTR of FXR1 shows a high similarity with FMR1 and is highly conserved during evolution, while that of FXR2 shows no similarity with FMR1. No CGG repeat is present in the FXR1 sequence, while the 5′ UTR of FXR2 contains a short $(CGG)_4$ unit.

FXR1 has seven isoforms with the two major ones having a predominant mRNA, 2.2 to 2.4 kb in size. The protein FXR1P has a molecular mass of respectively 70 and 78 kDa. There is a tissue-specific alternative splicing for FXR1 pre-mRNA in the 3′ carboxyl part. The *FXR2* gene generates a 3 kb-sized mRNA and the protein FXR2P has a mass of 95 kDa.

The expression pattern of FXR1P and FXR2P shows some similarities but also important differences with that of FMRP. In the testis, FMRP is only expressed in the spermatogonia, whereas FXR1P is expressed in postmeiotic spermatides at high levels, especially in the microtubules of sperm tails, and FXR2P is expressed in the tubuli seminiferi. A specific isoform of FXR1P is highly expressed in the muscles and the heart, where FMRP expression is nearly absent. In the brain, both homolog proteins are expressed in neuronal cytoplasm. In fragile X patients, similar expression levels of FXR1 and FXR2 are noticed in all tissues compared to controls.

On the basis of the sequence similarity between FMR1, FXR1, and FXR2, it has been suggested that FXR1P and FXR2P may have a similar function in the cell as FMRP and can partially compensate for its loss in fragile X patients, explaining the relatively mild phenotype of patients. Similarities include the localization in the cytoplasm, the association with polyribosomes, and the capability to bind RNA. In addition, both the paralog proteins can form homodimers and heterodimers with each other and with FMRP (Fig. 7), though, like FMRP, FXR1P, and FXR2P are predominantly cytoplasmic proteins, with some expression observed in the nucleus. FXR1P is able to shuttle between the nucleus and the cytoplasm, while FXR2P and some of the isoforms of FXR1P shuttle between the nucleolus and the cytoplasm. However, though some functional redundancy seems likely, differences between the FXR proteins and FMRP are also apparent. Unlike FMRP, FXR1P and FXR2P do not inhibit translation and have a different localization in some tissues. Moreover, it is unclear whether FXR1P and FXR2P can bind G-quartet-containing mRNAs to the same extent as FMRP.

6 Amino-terminal Interacting Proteins

Using the N-terminal domain of FMR1 containing the NLS, Bardoni et al. (1999) identified a novel protein that interacts with FMRP by a yeast two-hybrid assay (Fig. 7). The interacting protein was called NUFIP (nuclear FMRP interacting protein). It shows no homology with known proteins in the databases. NUFIP maps to chromosome 13q14, while a pseudogene maps to chromosome 6q12.

NUFIP contains two C_2H_2 zinc finger motifs and an NLS. The protein is mainly localized in the nucleus in a dotlike distribution but is also observed in the cytoplasm, where it associates with ribosomes. NUFIP interacts with FMRP both via the N-terminal and the C-terminal half, suggesting the presence of two protein-interacting regions. Despite the fact that the 5′ region of the *FMRP* gene, used as bait to pick up NUFIP, is highly similar between FMRP, FXR1P, and FXR2P, no interaction between NUFIP and the other FXR proteins could be detected. The mouse NUFIP shows a 95% homology with the human NUFIP and has an expression pattern comparable with that of FMRP, with high expression in the neurons of the hippocampus and the cortex, and in the Purkinje cells of the cerebellum, but lower expression in the granular cell layer. No expression was detected in glia cells. NUFIP is also expressed in fibroblasts and lymphoblasts. Not only is the expression pattern of NUFIP similar to that of FMRP but, in addition, the RNA-binding capacities of NUFIP do resemble those of FMRP as NUFIP binds with high efficiency to poly(G), with less efficieny to poly(U), and shows no affinity to poly(A) or poly(C) homopolymers. The RNA binding domain of NUFIP has not been identified yet.

More recently, two additional FMRP interacting proteins, named CYFIP1 and CYFIP2 (cytoplasmatic FMRP interacting protein 1 and 2), were isolated. CYFIP1 and CYFIP2 are 88% identical on protein levels and both are conserved during evolution but do not show similarities with genes in the database. The CYFIP proteins are expressed in the synaptic terminals of neurons in the brains, where it colocalizes with FMRP to ribosomes in the cytoplasm. The first coiled coil region of FMRP, encoded by exon 7 and mediating FMRP–protein interaction, is involved in the interaction of FMRP with CYFIP proteins (Fig. 7). Despite the high sequence similarity between the CYFIP proteins, CYFIP1 interacts only with FMRP, whereas CYFIP2 interacts with FMRP, FXR1P, and FXR2P. Not much is known about the function of the CYFIP proteins, but CYFIP1 appeared to be an interactor of the Rac1 protein, a member of the Rho–GTPase family, which plays a role in maturation and maintenance of dendritic spines by controlling the actin cytoskeleton.

7 Animal Models

7.1 Comparison between Species

Orthologs of the *FMR1* gene have been identified in different species such as mouse, rat, chicken, *Xenopus laevis*, *Danio rerio*, monkey, and *Drosophila*. The protein is well conserved between species. The murine, frog, chicken, and fly proteins are 97, 86, 92, and 31% identical to the human FMRP respectively. Homology is nearly 100% within the KH domain, while a lower similarity in the RGG box region is observed. Outside the coding region, the 3′ UTR is well conserved among species. The 5′ UTR region is highly GC-rich in all species analyzed, and a CGG repeat has been detected in most mammals. Chicken contains a 99-unit-long CCT repeat in place of the CGG repeat, flanked on both sides by dinucleotide repeats. No instability upon generational transmission was observed in these repeats in species other than man and monkey.

7.2 What Have We Learned from the Mouse Model?

As in humans, the murine *FMR1* gene is located on the X chromosome. All functional domains present in the human protein, 2 KH domains, an RGG box, two coiled coils, an NLS, and an NES are well preserved (Fig. 9). In the 5′ UTR, a triplet repeat containing 9 to 11 CGG repeats has been identified, depending on the mouse strain, interspersed by 1 CGA triplet. No fragile site and no spontaneous CGG-repeat instability have been observed in the mouse. The expression pattern of the murine *FMR1* gene is comparable with that of the human gene with abundant expression in the testis and the hippocampus.

Approximately 10 years ago, a knockout mouse model was constructed. Using homologous recombination, the Fmr1 sequence was interrupted by a neomycin cassette in exon 5 of the gene. Although the knockout mutation in the mouse *FMR1* gene differs from the dynamic mutation in most fragile X patients, both mutations lead to the same result: absence of protein product. The fragile X knockout mouse is fertile, and visual inspection revealed no obvious abnormalities. It has been subjected to a wide range of pathological, physiological, and behavioral tests.

7.2.1 Macroorchidism

Macroorchidism is present in the great majority of fragile X patients after puberty. In the knockout mouse, macroorchidism can be observed from day 15 after birth, increasing to a difference of 30% in weight at half a year of age. Similar to observations in human patients, pathological observation revealed no structural abnormalities in the testis of the knockout mouse. It was concluded that increased Sertoli cell proliferation in the fragile X mice in a well-defined period shortly before and after birth leads to higher spermatogenic cell number and testicular weight.

7.2.2 Cognitive Testing

Spatial learning in mice can be measured using the Morris water-maze test. In this test, mice have to find a hidden platform in a basin filled with opaque water during 12 learning trials. In the reversal phase, the platform is moved to the opposite position in the basin, and mice have to find the platform in its new position during four additional trials. It is particularly in this reversal phase that mild learning deficit is observed in the knockout mice. Similar observations are reported when mice were tested using the plus-shaped water maze and the terrestrial radial maze. The nature of the spatial deficit is not clear. The deficit may point to hippocampal defects, but other brain areas can also play a role in the observed differences in this reversal test.

7.2.3 Motor Activity and Anxiety

Fragile X patients are reported to be hyperactive and anxious. Fragile X knockout mice are more active than their control littermates. However, as the difference in activity between groups is mild and variance within groups is high, hyperactivity may be too small to measure when registered during a single time period as illustrated in Fig. 10.

A seemingly contradictory observation is that Fmr1 knockout mice displayed increased anxiety-related responses in the exploratory behavior test, whereas lesser anxiety is reported when measured in the open field test. However, no difference in anxiety was registered in the elevated plus

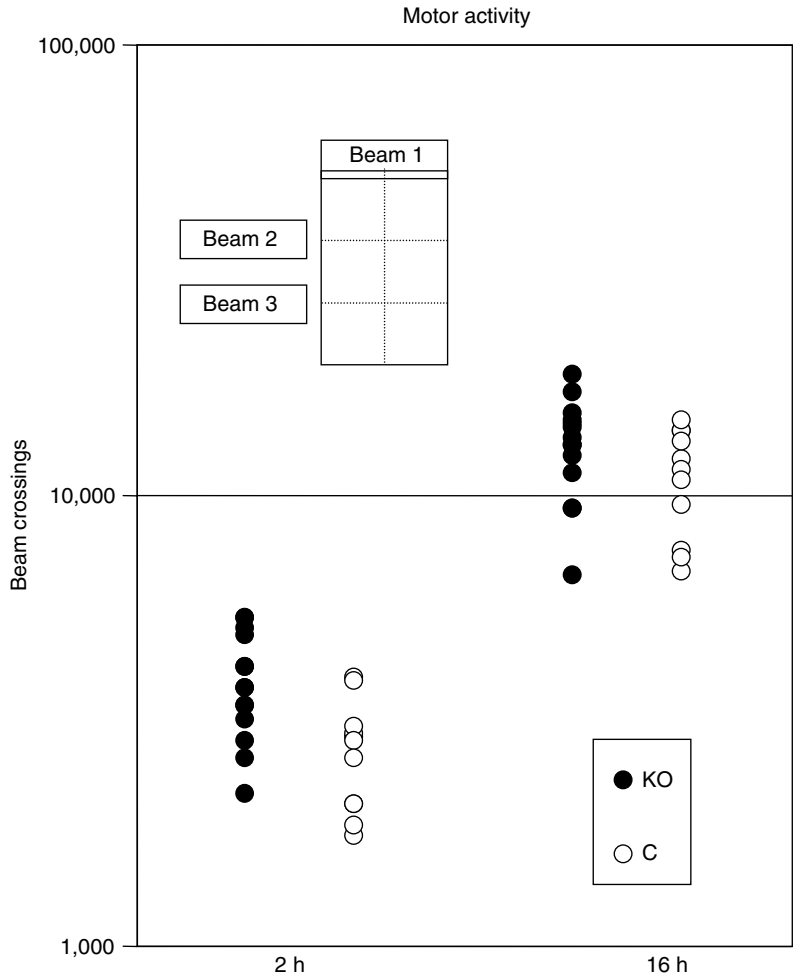

Fig. 10 Motor activity testing of the fragile X knockout mouse in comparison with control littermates. In one experiment, the total number of beam crossings was significantly elevated after 2 h of registration ($P < 0.005$), while after 16 h no statistical difference (N.S.) between both groups was observed. When the individual data were considered (black circles, knockout; white circle, control), it is noticed that a single outlier in the group of individual mice influenced the test result.

maze, considered to be the most suitable test to measure anxiety.

7.2.4 **Acoustic Startle Reflex**

The acoustic startle response is a behavioral tool to assess brain mechanisms of sensorimotor integration and is mediated by neurons in the lower brainstem. The knockout mice exhibited increased auditory startle-response amplitudes to low-intensity stimuli and decreased responses to high-intensity stimuli. The increased response to low-amplitude stimuli is compatible with the hyperarousal of fragile

X patients, while the decreased reactivity of the fragile X knockout mouse to high-amplitude stimuli is compatible with the decreased functioning of the neuronal connections in fragile X patients.

Prepulse inhibition was also affected in fragile X mice. In this variant of the acoustic startle response, a prepulse preceding the stimulus itself suppresses the response. Prepulse inhibition is dependent on a more complex forebrain circuitry. Inhibition was stronger in fragile X knockout mice compared to controls, suggesting involvement of the forebrain pedunculopontine nucleus pathway in fragile X syndrome.

7.2.5 Audiogenic Seizures

Spontaneous seizures are observed in more than 20% of the fragile X patients. These spontaneous seizures are never observed in the knockout mouse, but an increased sensitivity to epileptic seizures in response to auditory stimuli is detected in the knockout mouse. This may indicate that absence of Fmrp results in increased cortical excitability and is consistent with the sensory hypersensitivity of fragile X patients.

7.2.6 Neuroanatomy and Physiology of the Knockout Brain

Magnetic resonance studies of mouse brains did not reveal size differences in brain areas reported to be of abnormal size in human patients. As in human fragile X patients, impaired neuronal maturation is observed in the knockout mice. In cortical layer V of knockout mouse brains, pyramidal neurons have more elongated, thin, immature, and tortuous spines along the dendrites. In addition, a trend toward a higher spine density, characteristic for human fragile X patients, was observed. Since the knockout mice have an excess of immature spines, synaptic connectivity may be impaired. This may suggest that the fragile X protein is required in synaptic pruning and maturation processes in neurons, although at present it has not been established whether the neural abnormalities are the cause or the consequence of the mental retardation.

A detailed study of the hippocampus did reveal possible subtle neuroanatomic abnormalities. Sections through the hippocampus revealed excessive sprouting of the intra- and infra-pyramidal mossy fibers in subfield CA3 in knockout mice. This suggests increased axonal branching and synaptogenesis in the knockout mouse, perhaps related to the increased sensitivity to seizures. However, a decrease in size of the mossy fibers in the same hippocampal area was reported in an independent study. The reason for the discrepancy between both studies is not clear but could be related to strain differences. FVB mice with an unusually small CA3 subfield were used in the first-named study, whereas C57BL/6 mice with a relatively large CA3 subfield were used in the second study.

Detailed studies of dendritic processes of spiny stellate neurons in barrels, the cylindrical arrangements of neuronal cell bodies that define processes in the somatosensory cortex for the large facial whiskers, revealed additional subtle abnormalities. During normal development, dendritic processes extend in all directions from the cell body. Branches directed toward the interior of the barrel continue proliferating during development and those directed away from the interior are withdrawn. In knockout mice, no differences were observed for branches directed toward the barrel interior, while the branches

directed away from the interior remained more extensive compared to the controls.

Metabolic rates are also altered in the knockout mouse. Qin et al. (2002) measured the cerebral metabolic rates for glucose, CMR_{glc}, as an indicator of the level of functional activity in 38 brain regions of fragile X knockout mice and wild-type littermates. In 26 of the 38 regions, the CMR_{glc} level was significantly increased in the Fmr1 knockout mice, particularly in the regions of the limbic system and primary sensory and posterior parietal cortical areas. Interestingly, these areas are involved in motor activity and exploration, processes that are affected in the knockout mice. Thus, the increased level of the energy metabolism in cortical structures correlates with abnormal dendritic spine morphology and an increased excitatory state.

7.2.7 FMRP is Involved in Long-term Plasticity

Long-term potentiation (LTP), a long-lasting increase in synaptic efficiency, is believed to be involved in learning and memory. No altered LTP was measured in the hippocampus of the knockout mouse, but Li et al. observed severely reduced LTP when measured in the cortex. Reduced LTP could be correlated with a decreased quantity of GluR1 expression in the central synapses.

Long-term depression (LTD), a second form of hippocampal synaptic plasticity, is the opposite of LTP. It is triggered by the activation of group 1 metabotropic glutamate receptors. LTD appeared significantly enhanced in the hippocampus of the knockout mouse. While at first an unexpected finding, increase in LTD is consistent with the finding that Fmrp is a negative regulator of translation. As LTD is protein synthesis–dependent, absence of the translational inhibitor, FMRP, may inhibit the protein synthesis necessary for LTD (Fig. 11).

Since LTD and LTP are involved in learning and memory, it is tempting to speculate that abnormalities in synaptic connections in the knockout mouse may be related to the cognitive deficits in the fragile X syndrome.

7.2.8 FXR1/FXR2 Knockout Mice

It could be speculated that the abnormalities observed in the fragile X knockout mouse are relatively mild because the paralog genes *Fxr1* and *Fxr2* partially take over *Fmrp* function. Knockout mice for both paralog genes have been generated. Mice homozygous for the *Fxr1* knockout die shortly after birth because of respiratory problems (Siomi, personal communication). Mice heterozygous for the *Fxr1* mutation seem to be lighter and smaller than control littermates but not much is known about their phenotype. The *Fxr2* knockout mouse is viable and fertile and shows no obvious abnormalities. It has been subjected to a similar range of behavioral and pathological tests as the fragile X knockout mouse. Like the *Fmr1* knockout mouse, the *Fxr2* knockout mouse shows no obvious pathological abnormalities, is hyperactive, and performs poorly in the Morris water-maze test. Double or triple mutants of *Fmr1*/*Fxr* mice have not been described as yet, but such multiple knockouts may show us more of the possible redundancy in function of the Fxr proteins.

7.3 What Have We Learned from Drosophila?

7.3.1 The Ortholog, dFmr1

dFmr1, the *Drosophila melanogaster* ortholog of the *FMR1* gene, appears to

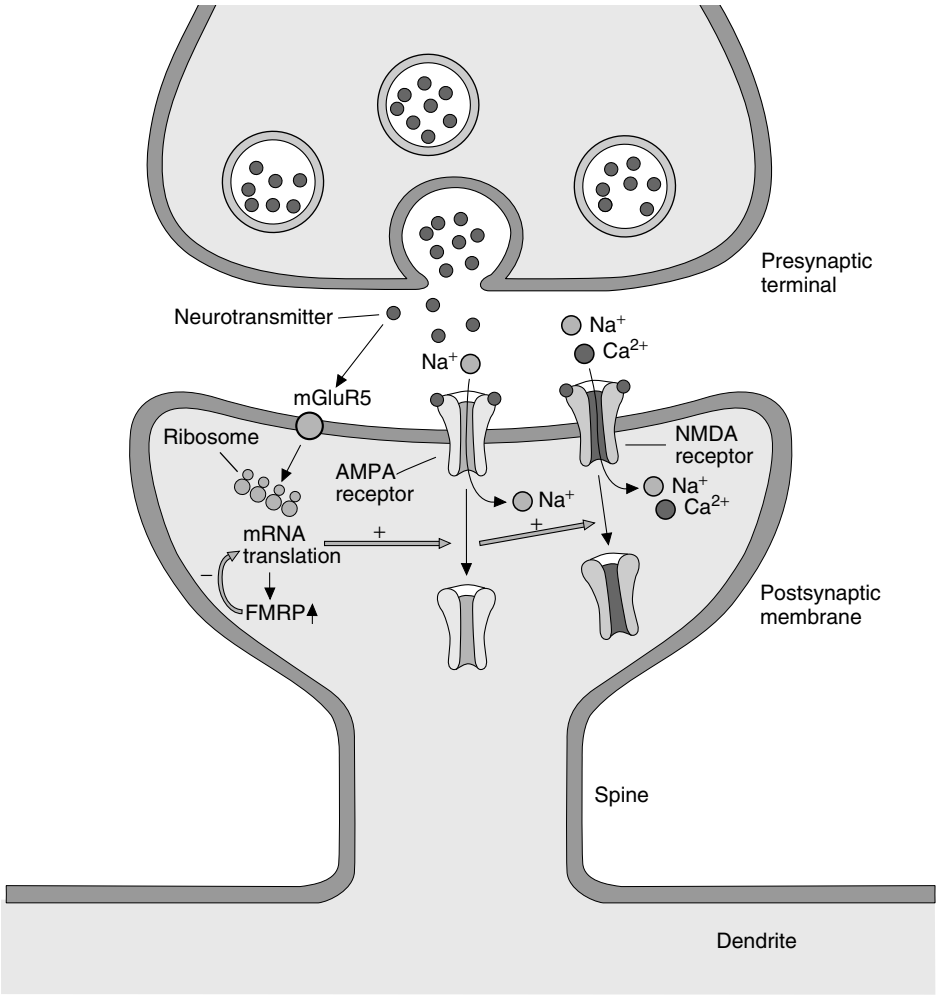

Fig. 11 Hypothetical model of the regulation of FMRP translation in a hippocampal synapse adapted from Huber et al. (2002). Stimulation of mGluR5 induces local mRNA synthesis. This results in novel protein synthesis that, in turn, stimulates the internalization of the AMPA and NMDA glutamate receptors, both essential for long-term plasticity. One of the proteins stimulated by mGluR5 activity is FMRP. As FMRP is a negative regulator of transcription, an increase in FMRP may result in a local decrease in mRNA translation. The resulting decrease in protein synthesis may slow down the internalization of the glutamate receptors, resulting in an increase in LTD.

be the only gene of this protein family in *Drosophila* with equal similarity to FMR1, FXR1, and FXR2 (Fig. 9). No CGG repeat is present in the 422-bp-long 5′ UTR region. Alternative splicing in dFmr1 occurs across the gene giving rise to different splice forms, but nothing is known about the expression of these splice products yet.

Like the human FMRP, the dFmr1 protein contains 2 KH domains, an RGG box with 50% identity to the human FMR1 RGG box, an NES, and an NLS. The dFmr1 NES shows little sequence conservation when compared to human FMRP and it remains to be determined whether it is a functional nuclear export signal. The region involved in the binding of FMRP to the 60S ribosomal subunit is also present in dFmr1.

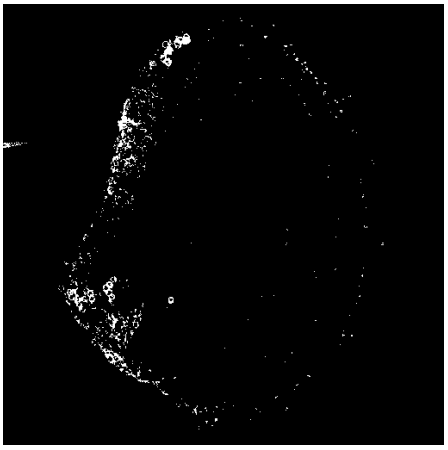
The protein can be observed in the cytoplasm, but a nuclear localization has not been detected. dFmr1 is expressed in early embryo starting from gastrulation. It is highly expressed in neurons but not in glia. It is not enriched in synapses. dFmr1 is moderately expressed in muscles, in presynaptic motor neurons, and in postsynaptic muscles during embryonic development and in the larvae.

Using heteropolymer binding essays, dFmr1 shows high affinity for poly(G), weaker affinity for poly(U), and no affinity for poly(C) and poly(A), characteristics identical to the human protein. Point mutations have been introduced in the highly conserved isoleucine residues, corresponding to the human Ile304Asn mutation, within each of the KH domains (I244N and I307N). Like mutated human FMRP, mutated dFmr1 loses the capacity to bind poly(U); dFmr1 binds with high capacity to human FMR1, but shows only moderate binding capacities with FXR1 and FXR2 and with itself.

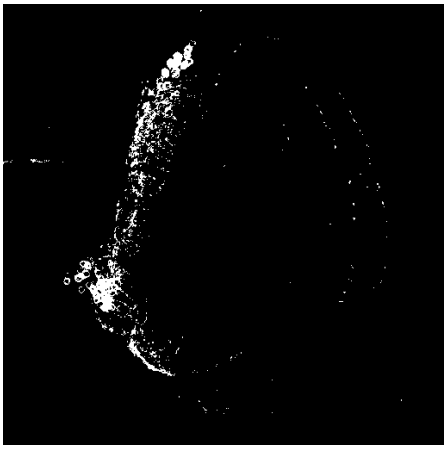
7.3.2 dFmr1 is Involved in Neuronal Maturation

Different mutant flies, including dFmr1 null mutants, dFmr1 overexpression mutants, and I244N and I307N KH point mutants, have been constructed to study the role of dFmr1 in *Drosophila*. The introduction of dFmr1 null mutants is not lethal, but some mutants fail to eclose properly, and only a few ''escapers'' survive. Overexpression of dFmr1 leads to severe rough-eye phenotype, whereas null mutants have no detectable effect in the structure of the eye. Photoreceptor development and function are not effected by loss of dFmr1, but overexpression of dFmr1 in the antennal disc of the eye causes apoptosis.

As observed in humans and mice, absence of dFmr1 and even different concentrations of dFmr1 compared to controls causes aberrant synaptic growth and plasticity. While overexpression of dFmr1 gives undergrowth of synapses and causes presynaptic enlargements of single synaptic boutons of twice the size, the null mutant of dFmr1 shows synaptic overgrowth and overelaboration of synaptic terminals but has no visible effect on the size of the synaptic boutons. Null mutants of dFmr1 exhibit aberrant small ectopic neurite branches, probably causing a misregulation of the intrinsic branching program. There is also a mistargeting of axons and looping fibers, potentially because of guidance defects. In dFmr1 null mutants, fiber extension abnormal morphology in the dorsal-cluster (DC) neurons is observed, as shown in Fig. 12. The level of dFmr1 determines the severity of the phenotype. The phenotype of



(a)



(b)

Fig. 12 Illustration of abnormal neuronal migration in *Drosophila* dFmr1 null mutant. Comparison of (a) heterozygous with (b) homozygous mutants shows a reduction in the number of dorsal-cluster neuron axons crossing from the lobula into the medulla. This finding suggests that in dorsal-cluster neurons, dFMR1 is required for proper extension and pathfinding of axons. (Photograph kindly provided by Katsu Okamura and Haru Siomi.)

the overexpression mutant is more severe than that of the loss-of-function mutant. dFmr1 overexpression caused a complete failure of axon extension from the lobula to the medulla. Overexpression of an I307N mutant dFmr1 causes defects similar to those observed in loss-of-function mutants but are less severe. These findings suggest that dFmr1 acts as an inhibitor of axon extension and as a regulator of axon growth and synapse formation in the cell.

7.3.3 MAP1B may be Involved in the Fragile X Syndrome

MAP1B is a protein that regulates the growth of dendrites, axons, and synapses. The *Drosophila* homolog for MAP1B has been identified as futsch. Using dFmr1-specific antibodies, futsch mRNA could be coprecipitated, suggesting that it may be part of the dFmr1–mRNP complex. MAP1B has also been identified as an *in vivo* target of FMRP and its mRNA contains a G-quartet. The level of futsch mRNA in *Drosophila* is inversely related to the level of dFmr1. Null mutants of dFmr1 display an increase in futsch mRNA, while overexpression mutants show a decrease in futsch-mRNA level. Overexpression of futsch in the fly causes neuromuscular junction overgrowth and increased bouton number, synaptic area, and branching. Introducing double futsch/dFmr1 null mutations rescued the structural and functional defects compared to dFmr1 mutant flies. This may suggest that dFmr1 regulates synaptic maturation and plasticity by functioning as a translational repressor of futsch mRNA.

7.3.4 dFmr1 is Involved in Circadian Rhythm Regulation

Most dFmr1 loss-of-function mutant flies develop until the pharate adult stage

but fail to eclose in the early morning. Moreover, while wild-type flies eclose during the early morning, dFmr1 null mutants may eclose at all times of the day. This suggests a defect in the circadian rhythm. This could be demonstrated by activity measurements. dFmr1 mutants show severely decreased activity levels without any day–night periodicity when the frequency with which flies cross an infrared beam was measured in the locomotor activity test, whereas wild-type flies exhibit a rhythmic pattern of rest and activity during a 23.5 h circadian cycle. The circadian defect was rescued by introducing the wild-type *dFmr1* gene as a transgene into the null mutant, while overexpression of dFmr1 lengthened the circadian pattern. Futsch mutants and dFmr1/futsch double mutants have no circadian defect and no change in locomotor activity or strength of rhythmicity.

Independently, Dockendorff et al. (2002) and Morales et al. (2002) concluded that clock genes are not affected in the dFmr1 mutant flies, suggesting that the dFmr1 mutations may have a strong effect on the pathway downstream from the endogenous clock components. Consistent with this hypothesis, the amplitude of the oscillations of the cAMP responsive-element binding protein, CREB, was found to be reduced in the mutant dFmr1 flies, suggesting that dFmr1 affects this known molecular output of the clock.

7.3.5 dFmr1 may be Involved in RNA Interference

dFmr1 was found to interact with L5 and L11, two large ribosomal subunit proteins. This demonstrates that, like the human fragile X protein, the dFmr1 protein associates with the 60S ribosomal subunit in *Drosophila*. The finding that not the dFmr1 region equivalent to the ribosomal binding domain in human FMRP but the 285–amino acid–long C-terminal end of the dFmr1 protein binds both ribosomal proteins was peculiar. The L5 protein is associated with 5S rRNA and forms a ternary complex by binding dFmr1 protein, suggesting that dFmr1 interaction with ribosomes takes place via the L11 protein and the L5/5S rRNA complex.

Two other proteins found associated with the dFmr1 protein in *Drosophila* are AGO2 and Dmp68. AGO2, a member of the Argonaute gene family, is an important component of the RNA-induced silencing complex (RISC), which recognizes and cleaves homologous mRNAs and mediates RNAi in Drosophila. Dicer, an enzyme that processes both miRNA and siRNA was also part of the complex containing AGO2 and dFmr1. p68, the human ortholog of Dmp68, unwinds short dsRNA in an ATP-dependent manner. Dmp68 is also required for efficient RNAi. Binding to both proteins suggests that dFmr1 may be involved in RNAi.

7.3.6 dFmr1 is Modified After Translation

CKII is a protein that phosphorylates nuclear and nonnuclear proteins and is highly conserved among species. Recent studies identified *Drosophila* casein kinase II as a protein phosphorylating dFmr1. The phosphorylated Ser406, located upstream of the RGG box in dFmr1, is a conserved amino acid between the fly and human FMR1 and FXR proteins. *In vitro*, replacement of the serine with alanine residues in dFmr1 protein and human FMRP abolishes CKII phosphorylation. Phosphorylation affects the efficiency of dFmr1 to form homomers and to bind other RNAs. Though phosphorylation was observed *in vivo*, the significance of this posttranslational modification remains unclear.

8
Phenotypic Effect of the Premutation

With the advent of a DNA-based diagnostic test, the study of premutation carriers has increased. Individuals with a premutation were initially thought to have no phenotypic manifestations. However, a number of studies have reported mild learning disabilities and emotional problems in a small subgroup of premutation carriers. Subsequent study demonstrated that these findings challenge the view that premutation carriers of FraX are unaffected. Premutation carriers have an increased risk for premature ovarian failure (POF) in females. Hundscheid et al. (2000) found that paternally inherited premutations were more likely to give rise to POF than maternally inherited premutations. This imprinting was not seen by the other groups, perhaps as a result of differences in the age of the study population or differences in inclusion criteria.

Recent studies in premutation carriers showed that the length of the CGG repeat has an inverse correlation with the FMRP levels, while it has a positive correlation with the FMR1 mRNA levels. Tassone et al. (2000) described premutation carriers with more than 100 CGG repeats having a reduced number of FMRP-positive cells but with at least fivefold elevated mRNA levels. These findings lead to the hypothesis of a compensatory mechanism. If the translation of FMR1 mRNA is less efficient or defective, low FMRP levels initiate via feedback induction FMR1 transcription. The resulting high FMR1 mRNA levels can only partially compensate the defect since normal FMRP levels are not achieved in cells with large premutation repeats. It is yet unknown whether FMRP levels itself are the crucial factor at work in this compensatory mechanism or whether it is coupled with the length of the CGG repeat. The expanded CGG repeat may lead to proportionally more open promoter conformation and consequently enhanced transcriptional activity. The normal FMR1 message levels in the mutant I304N cell line argues against a role for the lack of functional FMRP as a modulator of transcriptional activity of the *FMR1* gene. Another candidate for the upregulation of the FMR1 expression might be CGGBP1, a CGG-binding protein, that has shown the ability to regulate expression from the *FMR1* gene with a small CGG repeat. It can be hypothesized that in the case of an elongated CGG repeat, the CGGBP1 might be sequestered owing to extensive binding to the elongated repeat in the mRNA, resulting in a lowered active concentration of CGGBP1. A lower CGGBP1 concentration results in an increased FMR1 transcription.

Elevated FMR1 mRNA levels and/or reduced FMRP levels result in a phenotype recently described in older males carrying a premutation. These males may exhibit a unique neurodegenerative syndrome characterized by progressive intention tremor and ataxia. More advanced cases are accompanied by memory and executive function deficits, anxiety, and eventual dementia. MR imaging studies (T_2 signal) of the brain of symptomatic adult male premutation carriers showed a characteristic imaging, including hyperintensities of the middle cerebellar peduncle, cerebellar white matter lateral, superior, and inferior to the dentate nuclei, and volume loss involving the pons, mesencephalon, cerebellar cortex, cerebral cortex, white matter of the cerebral hemispheres, and corpus callosum. Neurohistological studies on the

brains of four symptomatic elderly premutation carriers demonstrated neuronal degeneration in the cerebellum and the presence of eosinophilic intranuclear inclusions in both neurons and astroglia. Furthermore, the inclusions showed a positive reaction with antiubiquitin antibodies, which suggests a link with the proteasome degradation pathway. The origin and constitution of the inclusions is poorly understood; however, elevated FMR1 mRNA levels have been proposed to be important for the formation of the inclusions.

A ''knock-in'' CGG triplet mouse has been generated that showed moderate CGG-repeat instability upon both maternal and paternal transmission. These mice showed an increased expression of FMR1 mRNA and a decreased expression of FMRP. The presence of ubiquitin-positive intranuclear inclusions was seen in neurons of the CGG expanded-repeat mouse. An increase in both the number and the size of the inclusions was observed during the course of life, which correlates with the progressive character of the cerebellar tremor/ataxia syndrome in humans. The observations in expanded-repeat mice suggest a correlation between the presence of intranuclear inclusions in distinct regions of the brain and the clinical features in symptomatic premutation carriers. The presence of inclusions in expanded-repeat mice supports a direct role of the *FMR1* gene, by either CGG expansion *per se* or mRNA level, in the formation of the inclusions, which in humans could have also be explained by a synergistic effect with another genetic locus.

These two clinical features are remarkable in that they are unique to premutation carriers, while full-mutation individuals are not affected. As the number of male premutation carriers is 10 times the number of males with a full mutation, the number of individuals who are at risk for the ataxia/tremor phenotype is large. It is not known whether females with a premutation suffer from this asimilar phenotype. If so, the age of onset can be expected to be later than in males.

9 The FMR1 Mutation

The FMR1 CGG repeat containing less than 50 CGGs is very stable. However, the CGG repeat above 50 repeat units is remarkably unstable. In the lower premutation range, the repeat can increase and decrease in size while staying in the premutation range. In the upper premutation range, the repeat can undergo massive expansions to more than several hundred repeats in full-mutation alleles. Two reports have suggested that full-mutation expansions are more likely to occur in male than in female offspring. However, a recent multicenter study found no significant differences in the proportion of full-mutation alleles in male or female fetuses.

9.1 Mechanism of CGG-repeat Expansion

Repeat instability is influenced by several factors. First, only transmission through the female germ line can give rise to a full mutation in the next generation. In contrast, transmission through the male germ line, irrespective of whether the male has either a full mutation or a premutation in his somatic cells, always reveals a premutation in the daughters. Second, the instability of premutation alleles in females is positively correlated

with the repeat size. They may expand to a different-sized premutation or a full mutation, larger repeats being more prone to expansion than smaller ones. Third, not only the length of the repeat is a risk factor for repeat instability but also the composition of the repeat. Cryptic AGG interruptions in the CGG repeat might provide stability to the repeat and instability might result from loss of AGG interruptions. In the normal population, the CGG repeat is interrupted by AGG trinucleotides, most often at positions 10 and 20. Loss of AGG repeats leads to alleles with longer perfect CGG-repeat tracts, which are prone to expansion, especially when the number of pure CGG units exceeds 30. Premutation alleles have either no or only one AGG repeat unit and are therefore unstable.

Loss of these AGG interruptions always occurs at the 3′ end of the repeat tract, and as a consequence, the longest pure CGG tract found within a premutation or full mutation is always located at the most 3′ end. The reason for this polar variation might involve the mechanisms underlying the repeat instability. The polarity of expansion of the CGG repeats in humans mimics the orientation-dependent instability of CGG repeats cloned into *Escherichia coli* and *Saccharomyces cerevisiae*. This finding suggests that a difference in leading- versus lagging-strand synthesis may be involved in repeat expansion.

Nonstructural, cis-acting factors may be related to a specific haplotype background as certain haplotypes of polymorphic markers in and around the *FMR1* gene are overabundant in fragile X chromosome. Dombrowski et al. (2002) found, in a population-based study, that gray zone alleles or protomutations (40–55 repeats) also are often associated with a specific fragile X syndrome-related haplotype. However, others, in a much smaller number of unstable events, did not find evidence for a specific haplotype as a risk factor for instability.

Studies in yeast and *E. coli* suggest that direction of replication, genetic background (including repair systems), transcription, and growth conditions have an influence on repeat instability too. Repeat instability is thought to be instigated by the formation of d(CGG) secondary structures. Several structures of the CGG repeat, such as hairpins and tetrahelical structures, have been suggested. The stability of the different structures seems to differ between both templates. Pausing of DNA polymerases at both hairpin and tetrahelical structures was observed *in vitro* as well as *in vivo*. This stalling of DNA polymerase might increase the probability of DNA polymerase slippage and this can result in expansion of the CGG repeat.

White et al. (1999) proposed the influence of RAD27, the yeast homolog of human FEN1, as a trans-acting factor on instability. RAD27 is necessary for correct processing of Okazaki fragments and its absence strongly increased CGG instability. Interestingly, White et al. (1999) did not observe any increase in the frequency of large expansion events when studying various CGG arrays in *mlh*1, *msh*2, *msh*3, and *msh*6 mutant backgrounds. In fact, it has been surprisingly concluded that repeat instability requires mismatch repair proteins.

It is likely that a multistep process is involved in repeat instability since it has never been observed that a normal repeat expands to a full-mutation repeat upon one transmission. The first step assumed to be involved in the initial expansion of trinucleotide repeats is slipped-strand

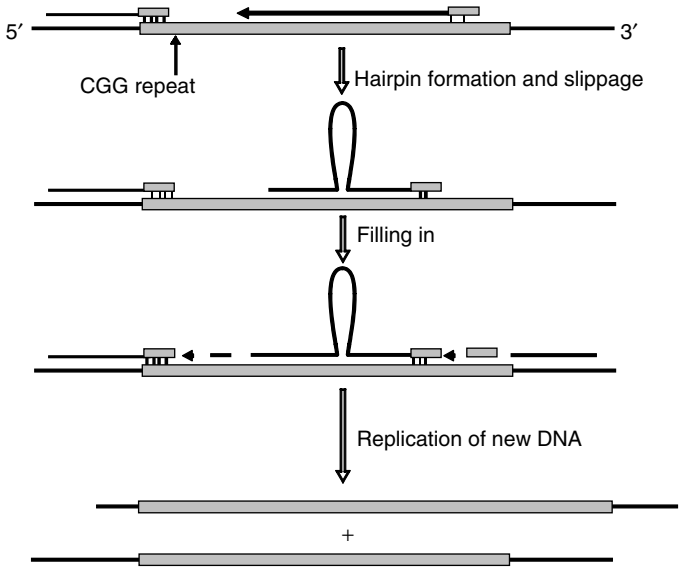


Fig. 13 Model for instability and expansion of the CGG repeat. During replication of the CGG repeat, a hairpin is formed followed by filling in of the gap, resulting in expansion of the repeat during multiple rounds of replication.

mispairing between DNA strands during DNA replication (Fig. 13) or possibly repair. Pausing of DNA polymerases allows the formation of secondary structures on the nascent lagging strand, which, if not correctly excised, should result in a small (up to 10 CGG-repeat units) increase. This slippage model can explain relatively small changes that occur within the normal and premutation alleles. The slippage model is the favored model, although other models, such as unequal meiotic sister chromatid exchange and/or gene conversion, are difficult to rule out.

For transition from premutation to full mutation, a different mechanism must be considered and it is thought that extremely unstable structures are formed in the nascent lagging strand owing to slippage on both ends of Okazaki fragments when these fragments contain solely CGG repeats. Incorrect repair will then lead to large expansions but might also result in contractions or deletions.

9.2 Timing of CGG-repeat Expansion

The timing of the repeat expansion and the difference observed in male and female transmission of the repeat is an intriguing feature of the mode of inheritance of the fragile X syndrome. How and when expansions from premutation to full mutation occur is not known.

Oocytes from full-mutation female fetuses have shown to contain a full mutation without a detectable premutation, suggesting a prezygotic model for expansion. In male fetuses with a full mutation in their somatic cells, the developing testes also show absence of FMRP in most cells. Testis tissue from a 13-week-old full-mutation fetus showed only full mutations

in the germ cells, while testis tissue from an older fetus showed evidence of both full and premutations in the germ cells. Adult full-mutation males show only a premutation in their sperm cells. The most likely model explaining these findings is the prezygotic model in which the full mutation is transmitted in the oocyte and the mutation in sperm-producing cells is regressed to a premutation size. While data by Malter et al. (1997) point to a prezygotic expansion, expansion occurring very early in embryogenesis (before day 3–5) cannot be ruled out.

The somatic mosaicism, often seen in patients, can be explained by instability that occurs postzygotically. Instability in the full-mutation range can occur, but also regression of the full mutation to a premutation can occur in some cells in somatic tissue. To study the exact timing of repeat expansion, an animal model will be required. The availability of an animal model to study the CGG-repeat instability will allow studying the repeat length at different time points during development.

10 Diagnostics

The identification of the *FMR1* gene and the mutational mechanism responsible for the fragile X syndrome introduced reliable DNA-based diagnostic tests, focused on the detection of the CGG-repeat amplification in patients and carriers, with or without associated hypermethylation. The two DNA methods to determine the CGG-repeat size are Southern blot hybridization and the polymerase chain reaction (PCR).

The availability of antibodies directed against FMRP allowed a diagnostic test to identify fragile X patients on the basis of the presence of FMRP in cells from unaffected individuals and its absence in cells from fragile X patients. Table 1 gives an overview of the different mutations in fragile X patients and carriers.

Tab. 1 Overview of the different mutations in fragile X patients and carriers.

Individual	Mutation	MR-associated CpG island	Number of repeats	Methylation of FMR-1	mRNA transcription	Risk of affected offspring
Normal	–	–	6–50	–	+	–
NTM	Pre-	–	50–200	–	+	–
Daughter of NTM/female carrier of a premutation	Pre-	–	50–200	–	+	+
Female carrier of a full mutation	Full[a]	70%[b]	>200	+[c]	+[d]	+
Male patient	Full[a]	+	>200	+	–	–

Note: MR: mental retardation; NTM: normal transmitting male.
[a] Somatic mosaicism is seen in about 40% of male patients (Nolin, 1994 #180). It is also observed in female carriers.
[b] In about 70% of females carrying a full mutation, mild-to-moderate mental retardation is found.
[c] Methylation is found on the inactive X and on the X chromosome carrying the full mutation.
[d] mRNA is only transcribed from the normal active X.

10.1 DNA Diagnostics

Very few fragile X cases have been reported without amplification of the CGG repeat and with either point mutations or deletions in other parts of the *FMR1* gene and DNA diagnostics is concentrating on detecting the repeat size.

The ability to detect both premutations and full mutations at the DNA level has made the diagnosis of the widespread disease available and has made genetic counseling possible through reliable detection of female and male carriers and patients, and can be used for prenatal diagnosis. Fragile X syndrome testing is based on the detection of CGG-repeat elongation in patients. This is based either on a Southern blot of leukocyte DNA digested with specific restriction endonucleases or on direct amplification of the CGG repeat using flanking primers.

10.1.1 Southern Blotting

The length of the CGG repeat can be determined by Southern blot analysis and mostly *EcoR*I or *Hind*III are used. Normal alleles will give a fragment of 5.2 kb. Longer fragments indicate the presence of a pre- or full mutation. Premutations are visible as fragments somewhat larger than 5.2 kb (up to 5.7 kb). Full mutations are visible as diffuse broad bands or ''smears'' owing to the presence of different repeat lengths (above 200 repeats) in different cells. Digestion with *Pst*I gives smaller fragments and, therefore, allows a better detection and sizing of premutations. By using an additional methylation-sensitive enzyme such as *Eag*I or *BssH*II, the length and the methylation status can be determined. This is applied to distinguish large premutations from small full mutations. For prenatal Southern blot diagnosis, digestion with a single enzyme (*Hind*III) is sufficient, as methylation has not occurred yet at the time (11 weeks) when chorionic samples were taken. DNA analysis is usually carried out using radioactive-labeled DNA probes; however, a good alternative is the use of nonradioactive (digoxigenin-labeled) probes followed by chemiluminescent detection.

10.1.2 Example of DNA Diagnostics in a Fragile X Family

Postnatal and prenatal diagnosis of fragile X syndrome can now be exercised with a high degree of accuracy by detecting the CGG-repeat amplification at the DNA level. Figure 14 shows a fragile X family in which premutations and full mutations are found. In the DNA of the grandmother (1) one normal 5.2 kb band (indicated by an arrow) is seen representing her 2 normal X chromosomes. The grandfather (2) is a normal transmitting male with a premutation of 70 repeats in the *FMR-1* gene; his DNA shows a band slightly larger than 5.2 kb. He passed his premutation on to his three daughters (4, 8, and 14) who are phenotypically normal carriers. Besides the 5.2 kb band of their normal chromosome, they have a premutation band of increased size (75 and 80 repeats). Daughter 4 has 1 affected daughter (6) who is mosaic for a premutation and a full mutation. Daughter 8 has 2 affected sons (12 and 13) with full mutations. Daughter 14 has one affected son (16) who is mosaic for a premutation and a full mutation.

10.1.3 PCR Amplification Analysis

Detection and accurate sizing of premutations can be done by PCR. The high CG content requires a specific PCR protocol. Initially, radioactivity was used to detect

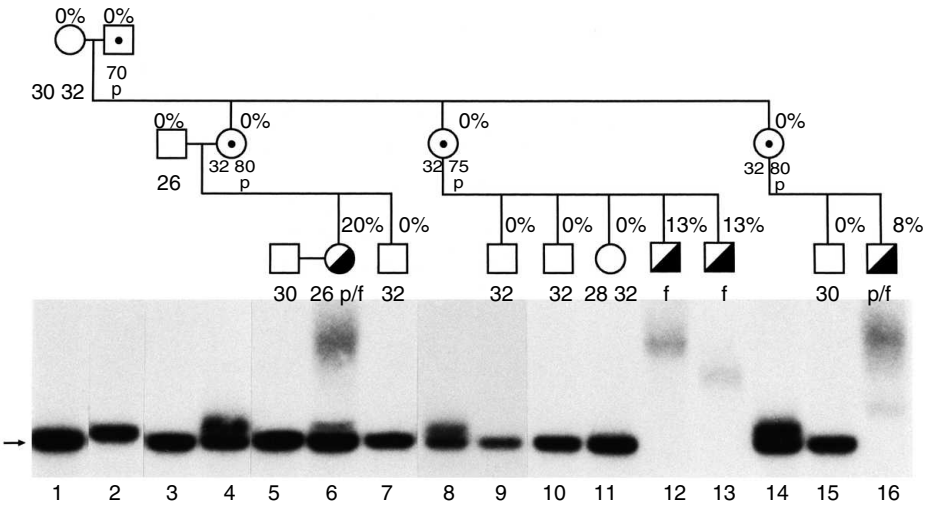

Fig. 14 Detection of the *FMR1* gene in a fragile X family by means of Southern blot analysis. {symbol individual 2} = normal transmitting male; {symbol individual 4} = normal female carrier; {symbol individual 6} = female carrier with cytogenetic expression; {symbol individual 12} = mentally retarded male; percentage of cytogenetic expression (if determined); number of CGG repeats for the different X chromosomes (determined by PCR) is indicated; p, premutation; f, full mutation. (Example of fragile X DNA diagnosis provided by Dr D. J. J. Halley and Dr A. M. W. van der Ouweland.)

the size of the PCR products. Alternatively, a nonradioactive method was developed using fluorescent-labeled precursors during the PCR amplification, and the size of the PCR product can be determined on an automated ABI sequencer. This last method gives a very accurate sizing of the PCR product in both males and females, starting from a very small amount of DNA.

Amplification of full mutations is very inefficient because it is difficult to amplify stretches of more than 100 to 200 CGG repeats, and it is therefore not a reliable method. Recently, an alternative PCR approach was described for the diagnosis of fragile X syndrome based on the methylation-sensitive conversion of C residues to U by bisulfite on single-strand DNA and subsequent amplification of the antisense strand with specific primers. A PCR with primers for methylated C residues will amplify the CpG dinucleotide region upstream of the CGG repeats exclusively in affected males. Moreover, the bisulfite treatment dramatically reduces the C + G component of the region; thus, the high T_m and the strong secondary structures are no longer obstacles for PCR amplification. This method can be used to identify males with a full mutation but cannot be applied for females with a full mutation owing to the presence of a nonmutated, methylated, inactive X chromosome.

10.2 Protein Test

Recently, alternative immunocytochemical tests have been described that are based on the direct detection of FMRP by a monoclonal antibody and the indirect visualization of antibody–antigen complexes

by alkaline phosphatase enzyme activity. The antibody test has the advantage of having the test result within 24 h, whereas routine DNA analysis by Southern blot generally takes more than 7 days.

A rapid method based on antibody detection of the FMR1 protein in cells of blood smears has been described and validated by Willemsen et al. FMRP in the cytoplasm of cells from unaffected individuals could be detected, whereas the cytoplasm of cells from affected males were not labeled for FMRP. For males, the diagnostic power of the test is high, because there is no overlap between the values of unaffected individuals and affected males with the full mutation. The diagnostic power of the test in identifying females with the full mutation is less specific compared to male patients. The X-inactivation process (lyonization) in cells from females with the full mutation may result in FMRP expression in a high percentage of their lymphocytes (up to 80%).

More recently, the protein test has been adapted for hair roots (Willemsen 1999), avoiding the need for blood drawing and allowing the analysis of the hair bulb cells that are of ectodermal origin and possibly less subject to selection effects in mosaic individuals than blood cells (of mesodermal origin). The diagnostic power of this new noninvasive test is high and it can be readily used to identify male patients. In addition, it was shown that the hair root test has the potential to serve as a prognostic indicator of the mental status in females with the full mutation.

11 Therapeutic Options

To study whether the fragile X syndrome is a potentially treatable disorder, rescue mice have been generated. Rescue mice are knockout mice in which an *FMR1* gene is introduced in the germ line by transgenesis. Introduction of FMRP as a cDNA under a CMV promoter in the Fmr1 knockout mouse resulted in expression of FMRP in the brain at roughly 50% of the control level. However, neither the phenotype, as measured by testicular weight, nor the cognitive capacities, as measured in the Morris water-maze, was rescued. Immunohistochemistry of the brain of the rescue mice showed FMRP expression in neurons, but also in nonneuronal cells, perhaps as a result of the CMV promoter used to drive FMR1 transcription.

Subsequently, Peier et al. (2000) created YAC transgenics, containing the whole human FMR1 with a large amount of flanking sequences, as a rescue model. Since the *FMR1* gene in the YAC is under the control of its own promoter, the gene is expressed in tissues similar to control mice. However, the overall level of FMRP seemed higher than that in control littermates. The testicular weight of the rescue mouse was restored, but the results of the behavioral test were controversial. In some tests, the rescue mice seemed ''overcorrected''; for example, in the open field test, knockouts were significantly more active than controls, but the rescue mice were significantly less active than controls.

The generation of these two rescue mice suggests that concentration of FMRP as well as cell specificity and timing of expression are very important.

11.1 CGG Methylation and Reactivation

Rare individuals with expanded but unmethylated repeats have been described. Such individuals are generally unaffected

with the fragile X syndrome, demonstrating that methylation and not repeat elongation *per se* causes the typical features of the syndrome. Addition of the demethylating agent 5-azadeoxycytidine to cultured lymphoblasts of fragile X patients did enable the production of FMRP by these cells. However, the percentage of reactivated cells was disappointingly low. As methylation in the cell is followed by deacetylation, it was hypothesized that a combination of demethylating and acetylating drugs might enhance demethylation of the CGG repeat. Indeed, a synergistic effect of the two types of drugs was demonstrated to enhance the reactivation of the FMRP production approximately fivefold.

Though reactivation of protein expression *in vivo* is a promising result, it should be realized that demethylating agents are highly toxic, and as long as no drugs are developed that specifically target the FMR1-CGG repeat and that are less toxic, the use of demethylating and acetylating agents in patients remains elusive.

11.2 AMPAkine Trial in Relationship with LTD Abnormality

Synaptic plasticity is believed to be involved in learning and memory, and it is therefore tempting to speculate that the enhanced LTD observed in fragile X mice (see Chapter 6.2.7) is potentially correlated to the cognitive deficits observed in the fragile X syndrome. LTD is directly dependent on the AMPA receptor. The availability of a group of drugs called AMPAkines that directly targets the AMPA receptor prompted a trial with one of these agents called CX516 in a small group of fragile X patients. So far, no negative side effects have been reported, but the results on ameliorating the symptoms of the fragile X syndrome are awaited.

12 Epilogue

More than a decade of research following the discovery of the causative gene has revealed a wealth of information regarding the possible role of the lack of the *FMR1* gene in the abnormalities of the fragile X syndrome. Functional domains identified in the fragile X protein suggested a role in RNA transport through the cell. Subsequent experimental evidence revealed that FMRP transports specific mRNAs as an mRNP particle along the dendrites to the synapses in neurons and plays a role in translation after binding to polyribosomes. A large amount of possible mRNAs bound by FMRP whose translation may be regulated by FMRP has been determined, including a specific group of mRNAs that contain a planar G-quartet structure. A subset of the bound mRNAs identified by different research groups plays an important role in synapse maturation and plasticity. Though certain neurotransmitters, hormones or stress, are able to influence the FMRP levels, the relevant *in vivo* stimuli, if any, are not known at present. In addition, the effect of the variable levels of FMRP on individual bound mRNAs is not known. However, in general FMRP seems to inhibit translation. Further functional studies have to determine the importance of each individual gene whose translation is influenced by FMRP levels in fragile X syndrome. Thus, misregulation or mistrafficking of a subset of mRNAs as a consequence of the absence of FMRP could lead to impaired synaptic maturation and plasticity and lie at the basis of

the mental retardation and associated abnormalities in fragile X syndrome. Further elucidation of the role of FMRP in patients and animal models may help us understand why absence of the fragile X protein leads to the pathogenesis of the syndrome.

Keywords

Antioxidant
A molecule that protects a biological target against oxidative damage.

Free Radical
Any species containing one or more unpaired electrons.

Oxidative Damage
The specific biomolecular damage caused by oxidative stress.

Oxidative Stress
An imbalance between the generation of reactive oxygen species and antioxidant protection, in favor of the former.

Polyunsaturated Fatty Acid
A fatty acid with two or more carbon–carbon double bonds in the side chain.

Reactive Oxygen Species
A collective name given to oxygen-containing radicals ($O_2^{\bullet -}$, $OH^{\bullet}$, peroxyl, alkoxyl) and some other nonradical derivatives of oxygen, such as H_2O_2.

Reactive Nitrogen Species
A collective name given to nitrogen-containing radicals ($NO^{\bullet}$, $NO_2^{\bullet}$) and some nonradical reactive derivatives, such as peroxynitrite ($ONOO^-$).

Free radicals and other ''reactive'' species are constantly generated *in vivo*, by ''accidents of chemistry'' and for specific metabolic purposes. The reactivity of different free radicals and ''reactive species'' varies, but some of them can cause severe damage to biological molecules, especially to DNA, lipids, and proteins. Antioxidant defense systems scavenge reactive species and minimize their formation, but are not 100% effective. Hence, repair systems exist to deal with molecules that have been oxidatively damaged. Damage to DNA by hydroxyl radicals appears to occur in all aerobic cells and might be a significant contributor to the age-dependent development of cancer. Similarly, oxidation of lipids by free radicals contributes to atherosclerosis and related vascular dysfunction, and to the vascular damage in diabetes. Free radicals may play a role in the aging process.

1 What is a Radical?

In the structure of atoms and molecules, electrons usually associate in pairs, each pair moving within a defined region of space around the nucleus. This space is referred to as an atomic or molecular *orbital*. One electron in each pair has a spin quantum number of $+1/2$, the other $-1/2$. A *free radical* is any species capable of independent existence (hence the term *free*), which contains one or more *unpaired electrons*, an unpaired electron being one that is alone in an orbital. The simplest free radical is an atom of the element hydrogen, with one proton and a single electron. Table 1 gives examples of other free radicals. The spectroscopic technique of *electron spin resonance* (ESR) is used to measure free radicals; it records the energy changes that occur as unpaired electrons align in response to a magnetic field. A superscript dot is used to denote free radical species (Table 1). Another widely used term is *reactive oxygen species*, which includes the oxygen radicals and certain oxidizing species that are not radicals, such as ozone (O_3) and singlet oxygen. A similar term *reactive nitrogen species* has been introduced to include radicals such as $NO^{\bullet}$ and $NO_2^{\bullet}$ (Table 1) and nonradicals such as peroxynitrite (see below).

2 Radicals *In Vivo*

The chemical reactivity of free radicals varies. One of the most reactive is the *hydroxyl radical* ($OH^{\bullet}$). Exposure of living organisms to ionizing radiation causes homolytic fission of O–H bonds in water (the major constituent of living cells)

$$H_2O \longrightarrow H^{\bullet} + OH^{\bullet} \qquad (1)$$

to give $H^{\bullet}$ and $OH^{\bullet}$. The hydroxyl radical reacts at a diffusion-controlled rate with almost all molecules in living cells. Hence, when $OH^{\bullet}$ is formed *in vivo*, it damages whatever it is generated next to – it cannot migrate any significant distance within the cell. The harmful effects on living organisms of excess exposure to ionizing radiation are thought to be largely initiated by attack of $OH^{\bullet}$ on proteins, carbohydrates, DNA, and lipids. For example, $OH^{\bullet}$ can abstract hydrogen atoms from fatty acid side chains in membrane lipids and initiate the process of lipid peroxidation.

2.1 Lipid Peroxidation

Initiation of peroxidation occurs by the attack of any species ($R^{\bullet}$) capable of abstracting hydrogen from a polyunsaturated fatty acid side chain in a membrane (such fatty acid side chains are more susceptible to free radical attack than are saturated or monounsaturated side chains).

$$-CH + R^{\bullet} \longrightarrow -C^{\bullet} + RH \qquad (2)$$

Species able to abstract hydrogen include $OH^{\bullet}$ and peroxyl radicals (Table 1). The carbon-centered radical that resulted from reaction (2) reacts rapidly with $O_2^{\bullet}$

$$-C^{\bullet} + O_2 \longrightarrow CO_2^{\bullet} \qquad (3)$$

and a fatty acid side chain *peroxyl radical* is formed. This can attack adjacent fatty acid side chains and *propagate* lipid peroxidation.

$$-CO_2^{\bullet} + -CH \longrightarrow -CO_2H + -C^{\bullet} \qquad (4)$$

Tab. 1 Examples of free radicals.

Name	*Formula*	*Comments*
Hydrogen atom	H^+	The simplest free radical
Trichloromethyl	$CCl_3^\bullet$	A carbon-centered radical (i.e. the unpaired electron resides on carbon. $CCl_3^\bullet$ is formed during metabolism of CCl_4 in the liver and contributes to the toxic effects of this solvent.
Superoxide	$O_2^{\bullet -}$	An oxygen-centered radical
Hydroxyl	$OH^\bullet$	An oxygen-centered radical. The most highly reactive oxygen radical known.
Thiyl	$RS^\bullet$	A group of radicals with an unpaired electron residing on sulfur.
Peroxyl, alkoxyl	$RO_2^\bullet$, $RO^\bullet$	Oxygen-centered radicals formed during the breakdown of organic peroxides.
Oxides of nitrogen	$NO^\bullet$, $NO_2^\bullet$	Both are free radicals. NO is formed *in vivo* from the amino acid L-arginine. NO_2 is found in polluted air and smoke from burning organic materials (e.g. cigarette smoke)

The chain reaction thus continues, and *lipid peroxides* ($-CO_2H$) accumulate in the membrane. Lipid peroxides destabilize membranes and make them "leaky" to ions. Peroxyl radicals can attack not only lipids but also membrane proteins (e.g. damaging enzymes, receptors, and signal transduction systems), and they can oxidize cholesterol.

2.2 The Hydroxyl and Superoxide Radicals

When $OH^\bullet$ is generated adjacent to DNA, it attacks both the deoxyribose and the purine and pyrimidine bases. Figure 1 shows the structures of some of the products generated by the attack of $OH^\bullet$ on the DNA bases: this wide range of products is characteristic of attack by $OH^\bullet$ and may be used to show that such attack has occurred *in vivo*. For example, if most or all of the compounds given in Fig. 1 are present in DNA that has been extracted from a tissue, this is strong evidence that the DNA has suffered attack by $OH^\bullet$. Such "$OH^\bullet$ fingerprint" experiments have been used to study the role of free radicals in DNA damage by radiation and toxic agents. It has also been found that there are larger amounts of these $OH^\bullet$-derived products in DNA from human cancerous tumors than from normal tissue. Whether this is due to increased $OH^\bullet$ formation or to decreased repair of the damage (see Section 7) remains to be evaluated.

Whereas $OH^\bullet$ is probably always harmful, other (less reactive) free radicals may often be useful *in vivo*. Free radicals are known to be produced metabolically in living organisms. For example, the free radical nitric oxide ($NO^\bullet$) is synthesized from the amino acid L-arginine by vascular endothelial cells, phagocytes, certain cells in the brain, and many other cell types. Nitric oxide is a vasodilator agent and an important neurotransmitter. It may also be involved in the killing of infectious organisms by macrophages in some mammalian species.

Superoxide radical ($O_2^{\bullet -}$) is the one-electron reduction product of oxygen. It is produced by phagocytic cells (neutrophils, monocytes, macrophages, eosinophils)

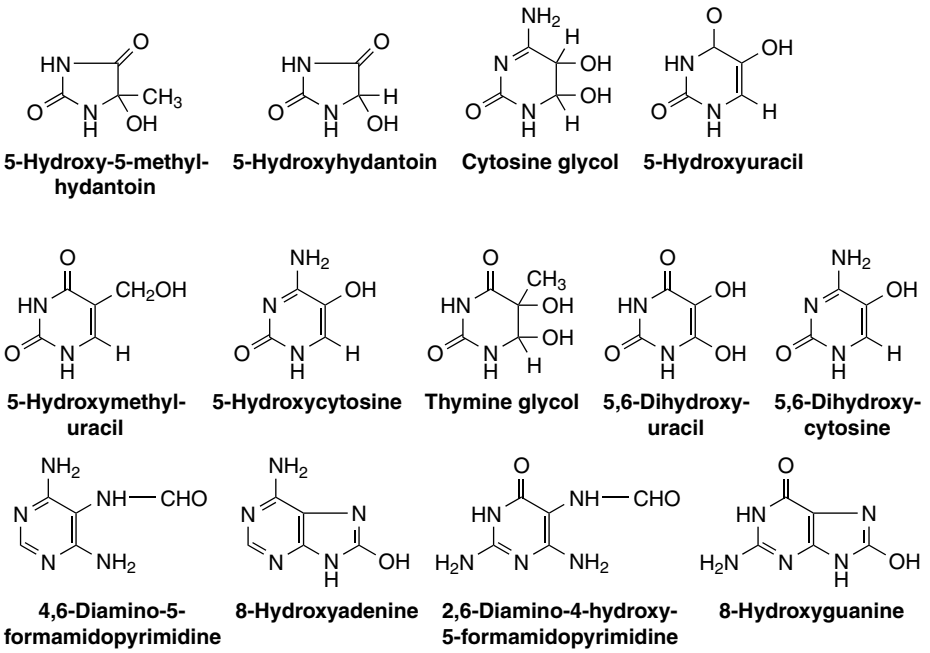

Fig. 1 Some products of hydroxyl radical attack on DNA bases.

and helps them to kill bacteria. Smaller amounts of extracellular $O_2^{\bullet -}$ can be generated, perhaps as an intercellular signal molecule, by several other cell types, including endothelial cells, lymphocytes, and fibroblasts. In addition to this deliberate metabolic production of $O_2^{\bullet -}$, some $O_2^{\bullet -}$ is produced within cells by mitochondria and endoplasmic reticulum. This is often thought to be an unavoidable consequence of "leakage" of electrons onto O_2 from their correct paths in electron transfer chains (i.e. an "accident of chemistry"), but others have argued that the H_2O_2 generated from $O_2^{\bullet -}$ signals the redox state of the mitochondria to the rest of the cell (see below).

Aerobic organisms also contain many "autoxidizable" compounds, compounds that react directly with oxygen to generate free radicals. For example, adrenaline (epinephrine) slowly reacts with O_2 to form $O_2^{\bullet -}$, which then oxidizes more epinephrine, setting up a chain reaction. These autoxidizable compounds presumably react with O_2 *in vivo*, providing another source of $O_2^{\bullet -}$.

2.3 Hydrogen Peroxide – A Nonradical

Most of the $O_2^{\bullet -}$ generated *in vivo* probably undergoes a dismutation reaction, represented by the overall equation:

$$2O_2^{\bullet -} + 2H^+ \longrightarrow H_2O_2 + O_2 \qquad (5)$$

Hydrogen peroxide (H_2O_2), a nonradical, resembles water in its molecular structure and is very diffusible within and between cells, probably crossing plasma membranes through the aquaporin channels. As well as arising from $O_2^{\bullet -}$, H_2O_2

is produced directly by the action of certain oxidase enzymes in cells, including amino acid oxidases and the enzyme xanthine oxidase. Xanthine oxidase catalyzes the oxidation of hypoxanthine to xanthine and of xanthine to uric acid. Oxygen is simultaneously reduced both to $O_2^{\bullet -}$ and to H_2O_2. Low levels of xanthine oxidase are present in many mammalian tissues, especially in the gastrointestinal tract. The levels of xanthine oxidase often increase when tissues are subjected to insult, such as trauma or deprivation of oxygen.

Like $O_2^{\bullet -}$, H_2O_2 has certain useful metabolic functions. For example, H_2O_2 is used by the enzyme *thyroid peroxidase* to help make thyroid hormones. H_2O_2 is involved in cell-signaling mechanisms. For example, in certain cell types it acts as a second messenger leading to displacement of the inhibitory subunit from the cytoplasmic transcription factor NF-κB. In lymphocyte cell lines, for example, H_2O_2 induces the expression of genes controlled by NF-κB. In some cellular systems, H_2O_2 mediates the effects of insulin and (transforming growth factor-β) TGFβ. How widespread and important these H_2O_2-dependent signaling systems are *in vivo* remains to be elucidated.

3 Radical Reactions

If two free radicals meet, they can join their unpaired electrons to form a covalent bond. Thus, for two hydrogen atoms,

$$H^{\bullet} + H^{\bullet} \longrightarrow H_2 \qquad (6)$$

and for $NO^{\bullet}$ and $O_2^{\bullet -}$,

$$NO^{\bullet} + O_2^{\bullet -} \longrightarrow \underset{\text{Peroxynitrite}}{ONOO^-} \qquad (7)$$

Peroxynitrite rapidly protonates to form peroxynitrous acid

$$ONOO^- + H^+ \longrightarrow \underset{\text{Peroxynitrous acid}}{ONOOH} \qquad (8)$$

ONOOH and its products of decomposition and reaction with CO_2, which appear to include some $OH^{\bullet}$ and $NO_2^{\bullet}$, can cause severe damage to proteins, lipids, and DNA. Peroxynitrite is an example of a "reactive nitrogen species."

However, when a free radical reacts with a nonradical, a new radical results; that is, a *chain reaction* is set up. Since most biological molecules are nonradicals, the generation *in vivo* of reactive radicals such as $OH^{\bullet}$ usually sets off chain reactions. For example, attack of $OH^{\bullet}$ on fatty acid side chains in membranes and other biological lipoproteins can abstract hydrogen, leaving a carbon-centered radical and initiating the process of lipid peroxidation (Section 2.1). Attack of $OH^{\bullet}$ on the DNA bases produces radicals, which then undergo complex reactions to generate the end products shown in Fig. 1. For example, the initial radical produced when $OH^{\bullet}$ attacks guanine at position 8 can then form 8-hydroxyguanine by electron loss, or can break down to 2,6-diamino-4-hydroxy-5-formamidopyrimidine (Fig. 1).

4 The Role of Transition Metal Ions

Neither $O_2^{\bullet -}$ nor H_2O_2 is very reactive, although they do react with certain cellular targets. For example, $O_2^{\bullet -}$ can inactivate aconitase and interfere with mitochondrial energy production, whereas H_2O_2 can inhibit the caspase enzymes important in apoptosis. Nevertheless, the limited reactivity of $O_2^{\bullet -}$ and H_2O_2 allows them to be used for such purposes as signal

transduction: a similar comment applies to the generally poorly reactive radical $NO^{\bullet}$, which plays essential roles *in vivo*. However, if $O_2^{\bullet -}$ and H_2O_2 come into contact with iron or copper ions, the noxious $OH^{\bullet}$ can be formed.

$$O_2^{\bullet -} + H_2O_2 \xrightarrow{\text{Fe or Cu catalyst}} OH^{\bullet} + OH^- + O_2 \qquad (9)$$

However, the chemistry involved is much more complicated than is suggested by this simple summary equation. Hence, the presence, in a biological system, of transition metal ions able to catalyze reaction (9) can cause $O_2^{\bullet -}$ and H_2O_2 to be damaging. Because $OH^{\bullet}$ cannot migrate any significant distance, the damage will occur at the sites at which the "catalytic" metal ions are present. That is, it is *site-specific* free radical damage. For example, if such metal ions are bound to DNA, and $O_2^{\bullet -}$ plus H_2O_2 reach the DNA, $OH^{\bullet}$ will be generated and will damage the DNA (Fig. 1). However, if the metal ions were bound to membranes, then lipid peroxidation could result (Section 2.1).

Another way of causing damage by $O_2^{\bullet -}$ is via $ONOO^-$ formation (see above). At normal physiological levels of $O_2^{\bullet -}$ and $NO^{\bullet}$, $ONOO^-$ formation appears slow. At sites of tissue injury, more $O_2^{\bullet -}$ is formed as a result of phagocyte recruitment, and more $NO^{\bullet}$ is produced, usually owing to elevated expression of the genes encoding the inducible nitric oxide synthase enzyme, iNOS. At these higher levels of $O_2^{\bullet -}$ and $NO^{\bullet}$, more $ONOO^-$ is formed. One of the reactions of ONOOH with proteins leads to nitration of tyrosine residues, and the formation of 3-nitrotyrosine is often used as a "biomarker" of $ONOO^-$ formation *in vivo*.

5 Antioxidant Defenses

Living organisms have evolved antioxidant defenses to remove excess $O_2^{\bullet -}$ and H_2O_2. *Superoxide dismutase* enzymes (SODs) remove $O_2^{\bullet -}$ by accelerating its conversion to H_2O_2 (Eqn. 5) by about four orders of magnitude at pH 7.4. Mammalian cells have a SOD enzyme containing manganese at its active site (MnSOD) in the mitochondria. A SOD with copper and zinc at the active site (CuZnSOD) is also present, largely in the cytosol, but some CuZn SoD is also present in the space between the inner and outer mitochondrial membranes.

Because SOD enzymes generate H_2O_2, they work in collaboration with H_2O_2-removing enzymes. *Catalases* convert H_2O_2 to water and O_2.

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \qquad (10)$$

Catalases are present in the peroxisomes of mammalian cells and probably serve to destroy H_2O_2 generated by oxidase enzymes located within these subcellular organelles. More important H_2O_2-removing enzymes in mammalian cells are the *glutathione peroxidases* (GSHPX), enzymes that require selenium (a selenocysteine residue residue, essential for enzyme activity, is present at the active site). GSHPX enzymes remove H_2O_2 by using it to oxidize reduced glutathione (GSH) to oxidized glutathione (GSSG). Glutathione reductase, a flavoprotein (FAD-containing) enzyme, regenerates GSH from GSSG, with NADPH as a source of reducing power (Fig. 2). Removal of H_2O_2 may also be achieved by thioredoxin-dependent systems. Thioredoxin is a small protein (Mr ~12 kDa) that can react with H_2O_2 to become oxidized in the presence of a peroxidase enzyme. A thioredoxin reductase, also a selenoprotein, regenerates the thioredoxin for reuse.

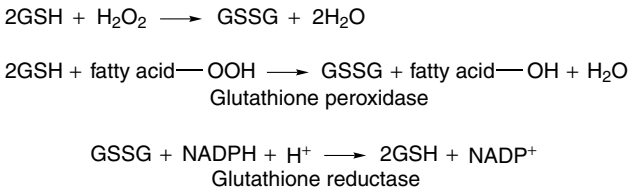

Fig. 2 The glutathione system. Reduced glutathione is a tripeptide, glutamic acid–cysteine–glycine. It is present at millimolar concentrations in most mammalian cells. In oxidized glutathione (GSSG), two tripeptides are linked by a disulfide bridge. Glutathione has several additional metabolic functions. Glutathione peroxidase can also destroy fatty acid (lipid–OOH) peroxides by converting them to hydroxy alcohols (lipid–OH). Mammalian cells additionally contain a phospholipid hydroperoxide glutathione peroxidase that can apparently perform the same reaction on lipid peroxides *within membranes;* how exactly it works is uncertain as yet.

The thioredoxin system additionally plays a key role in regulation of gene expression and cell function generally.

Another important antioxidant defense system consists of metal ion storage and transport proteins, which organisms have evolved to keep iron and copper safely protein-bound whenever possible, thus minimizing the occurrence of reaction (9).

Antioxidant defense enzymes are essential for healthy aerobic life. Because of impaired biosynthesis of certain amino acids, for example, SOD-negative mutants of *E. coli* will not grow aerobically unless given a rich growth medium. Even when so supplemented, SOD-negative *E. coli* cells grow slowly, suffer membrane damage, are abnormally sensitive to damage by H_2O_2 (perhaps because of reaction 9), and show a high mutation rate. In addition to antioxidant defense enzymes, some small-molecule free radical scavengers exist. GSH can scavenge various free radicals and ONOOH directly, as well as being a substrate for GSHPX enzymes. α-Tocopherol is the most important (but not the only) free radical scavenger within membranes and lipoproteins. α-Tocopherol inhibits lipid peroxidation by scavenging peroxyl radicals (Table 1), which are intermediates in the chain reaction described in Section 2.1:

$$\alpha - \mathrm{TH} + \mathrm{LOO}^{\bullet} \longrightarrow \alpha\mathrm{T}^{\bullet} + \mathrm{LOOH} \tag{11}$$

where $\alpha T^{\bullet}$ is the α-tocopherol radical and $LOO^{\bullet}$ is the peroxyl radical. Since $\alpha T^{\bullet}$ is less efficient at abstracting hydrogen than $LOO^{\bullet}$, the chain reaction of peroxidation is slowed down. Several biological mechanisms may exist for recycling $\alpha T^{\bullet}$ back to α-tocopherol, although none of them has yet been proved to operate *in vivo*. Likely mechanisms include the reaction of $\alpha T^{\bullet}$ with ascorbic acid at the surface of membranes and lipoproteins

$$\alpha\mathrm{T}^{\bullet} + \text{ascorbate} \longrightarrow \alpha\mathrm{TH} + \text{ascorbate}^{\bullet} \tag{12}$$

and/or with ubiquinol (reduced coenzyme Q) within membranes or lipoproteins:

$$\mathrm{CoQH_2} + \alpha\mathrm{T}^{\bullet} \longrightarrow \alpha\mathrm{TH} + \mathrm{CoQH}^{\bullet} + \mathrm{H}^{+} \tag{13}$$

$CoQH_2$ can also directly scavenge $RO_2^{\bullet}$ radicals. Antioxidant defense enzymes

exist as a balanced coordinated system in mammals. Thus, although SOD is an important defense, an excess of SOD in relation to the activity of peroxide-metabolizing enzymes can be deleterious. This has been shown by transfecting cells with human cDNAs encoding SOD. The consequences of excess SOD activity may be relevant to the clinical condition known as *Down syndrome* (DS), a point being explored by the use of transgenic animals, as indicated in Section 6.

6 Transgenic Animal Technology in the Study of Elevated SOD

Down's syndrome is the most common human genetic disorder, occurring once in every 600 to 800 live births. Defects that may be suffered by DS individuals include short stature, malformations of the skin around the eyes, and mental retardation. Patients who survive beyond their thirties show an increased risk of developing Alzheimer's disease. DS is usually caused by the presence of three copies of chromosome 21 (trisomy 21), one of whose genes encodes Cu/Zn-SOD. Patients with DS show some evidence of increased oxidative damage.

Does the elevated level of Cu/Zn-SOD cause, or contribute to, DS? Transgenic mice that overexpress human Cu/Zn-SOD activity in all tissues are found to be more resistant than controls to O_2 toxicity, consistent with a role of $O_2^{\bullet -}$ in this process. They are also more resistant than controls to certain toxins, but they have abnormal neuromuscular junctions in the tongue and show some of the other neurological defects characteristic of Downs syndrome.

7 Oxidative Stress and Repair Systems

Normally, the production of $O_2^{\bullet -}$ and H_2O_2 is approximately balanced by the antioxidant defense systems; that is, the antioxidants are not present in great excess. One reason for this may be that production of some $O_2^{\bullet -}$ and H_2O_2 is useful *in vivo*, for example, for signaling purposes. Indeed, some free radical damage to DNA, proteins, and lipids occurs constantly even in health, and it has been argued that the aging process involves cumulative free radical damage over the lifetime of a species. However, if antioxidant levels fall or production of $O_2^{\bullet -}$ and H_2O_2 increases, an imbalance occurs and *oxidative stress* is said to result. This may result in increased levels of oxidative damage to biomolecules.

Oxidative stress can result from the following phenomena:

- Depletion of antioxidants – for example, through inadequate dietary intake of α-tocopherol, ascorbic acid (vitamin C), sulfur-containing amino acids (needed for GSH manufacture), or riboflavin (needed to make the FAD cofactor in glutathione reductase).
- Excess production of oxygen-derived species – for example, by exposure to elevated O_2 concentrations, by the presence of toxins that are metabolized to produce free radicals, or by excessive activation of ''natural'' radical-producing systems (e.g. inappropriate activation of phagocytic cells in chronic inflammatory diseases, such as rheumatoid arthritis and ulcerative colitis).

Cells can tolerate mild oxidative stress, which often results in upregulation of the synthesis of antioxidant defense enzymes in an attempt to restore the balance. For

example, exposure of *E. coli* to toxins that increase $O_2^{\bullet -}$ production accelerates the biosynthesis of at least 40 different proteins. Nine of these (including MnSOD) belong to the same regulon, controlled by the *sox* locus, which contains two adjacent genes, *soxR* and *soxS*. Expression of *soxS* is increased by $O_2^{\bullet -}$, and it then leads to expression of *soxR*. The excess $O_2^{\bullet -}$ forms an excess of H_2O_2, which oxidizes the protein oxyR, leading to activation of the transcription of another panel of genes, including genes encoding catalase and glutathione reductase enzymes (Fig. 3). Because antioxidant defenses do not scavenge 100% of the radicals generated *in vivo*, some oxidative damage occurs.

This damage is continuously repaired, however, with the result that baseline levels of damage are kept low. Table 2 summarizes some of the repair systems known to exist. Failure of repair systems may contribute to the aging process.

8 Consequences of Oxidative Stress

Although most tissues can adapt to mild oxidative stress, severe oxidative stress can cause cell damage and death, by a series of interacting mechanisms. Thus, oxidative stress appears to cause an increase in the levels of "free" Ca^{2+} within cells, as well as "free" iron, which can lead to $OH^{\bullet}$ generation. Some of this $OH^{\bullet}$ generation seems to occur within the nucleus, so that DNA is attacked. The hydroxyl radical attacks DNA in a multiplicity of ways (Fig. 1); one of the main products of $OH^{\bullet}$ attack on the purine bases is 8-hydroxyguanine, a mutagenic lesion that

Treat with H_2O_2: Upon treatment with low doses, *E. coli* adapts and becomes resistant to high levels of H_2O_2 that normally would kill it. One of the adaptation mechanisms is as follows:

Treatment with H_2O_2
↓
Oxidation of oxyR protein
↓
Activation of transcription of genes to increase synthesis of at least eight proteins, including catalase and glutathione reductase.

H_2O_2 also activates expression of other protective genes in *E. coli*, by mechanisms not involving *oxyR*.

Treat with $O_2^{\bullet -}$: The H_2O_2 response system above may be activated as follows:

Treatment with $O_2^{\bullet -}$
↙ ↘
Formation of H_2O_2 and activation of the above response system
Activation of *soxR* and *soxS* genes, leading to increased synthesis of at least nine proteins, including MnSOD and a DNA repair enzyme

Fig. 3 Regulation of antioxidant defenses in *E. coli*.

Tab. 2 Repair of oxidative damage.

Substrate of damage	*Repair system*
DNA. All components of DNA can be attacked by $OH^{\bullet}$. Several other reactive oxygen species (ROS) attack guanine preferentially, as does ONOOH; H_2O_2 and $O_2^{\bullet -}$ do not attack DNA.	A wide range of enzymes exist that recognize abnormalities in DNA and remove them by excision, resynthesis, and rejoining of the DNA strand. There is some evidence that DNA repair capacity may decline in the elderly.
Proteins. Many ROS can oxidize – SH groups. $OH^{\bullet}$ attacks many amino acid residues. Proteins often bind transition metal ions, making them a target of attack by site-specific $OH^{\bullet}$ generation.	Oxidized methionine residues may be repaired by a methionine sulfoxide reductase enzyme. Other damaged proteins are destroyed by the cellular proteasome system. Proteasomal activity may decline in the elderly, and low activities have been found in brain tissues from subjects with Alzheimer's and Parkinson's diseases, where there is an accumulation of oxidized proteins.
Lipids. Some ROS (not including $O_2^{\bullet -}$ or H_2O_2) can initiate lipid peroxidation.	Chain-breaking antioxidants (especially α-tocopherol) remove chain-propagating peroxyl radicals. Phospholipid hydroperoxide glutathione peroxidase (Fig. 2) can remove peroxides from membranes. Normal membrane turnover can replace damaged lipids.

can lead to G → T transversions. An excessive rise in intracellular free Ca^{2+} can activate endonucleases and cause DNA fragmentation.

Several toxins impose oxidative stress during their metabolism. Carbon tetrachloride is one example (Table 1): it is metabolized *in vivo* by endoplasmic reticulum to produce a free radical (trichloromethyl peroxyl radical, $CCl_3O_2^{\bullet}$) that is efficient at initiating lipid peroxidation, by abstracting hydrogen from polyunsaturated fatty acid side chains (Section 2.1). Another is paraquat, a herbicide that causes lung damage in humans. Its metabolism within the lung leads to production of large amounts of $O_2^{\bullet -}$ and H_2O_2. Paraquat is reduced to a free radical by lung enzymes.

$$PQ^{2+} + e^{-} \longrightarrow PQ^{\bullet +} \qquad (14)$$

This radical then reacts very fast with O_2 in a nonenzymic reaction:

$$PQ^{\bullet +} + O_2 \longrightarrow PQ + O_2^{\bullet -} \qquad (15)$$

The paraquat is regenerated to repeat the cycle. Other examples of such ''redox cycling'' toxins are alloxan, diquat, and 6-hydroxydopamine. Cigarette smoking has many deleterious health effects, and oxidative stress is believed to be involved in several of these. Table 3 summarizes the mechanisms by which cigarette smoke can impose oxidative stress.

Oxidative stress can lead to increased levels of oxidative damage to biomolecules. For example, specific proteins undergoing oxidative damage in the brains of subjects with Alzheimer's disease have been identified. Hyperglycemia can cause

Tab. 3 Why cigarette smoking may impose oxidative stress.

Smoke contains many free radicals (both in the gas and tar phases), especially peroxyl radicals, that might attack biological molecules and deplete antioxidants, such as ascorbic acid and α-tocopherol.
Smoke contains oxides of nitrogen, including the unpleasant nitrogen dioxide ($NO_2^{\bullet}$), a free radical that can initiate lipid peroxidation.
The tar phase of smoke contains lipid-soluble hydroquinones, which may enter the tissues and the redox cycle. Some may also release iron from the iron storage protein ferritin, providing ''free'' iron to catalyze OH formation.
• Smoking may irritate lung macrophages, encouraging them to make $O_2^{\bullet -}$.
• Smokers' lungs contain more neutrophils than the lungs of nonsmokers, and smoke might activate these cells to make $O_2^{\bullet -}$.
• Smokers who eat poorly and drink more alcohol than nonsmokers may have an insufficient dietary intake of nutrient antioxidants.
• The effects of cigarette smoke on phagocytes are dose-related. Low levels may stimulate them, but high levels may poison phagocytes and so depress their activity.

severe oxidative stress, accounting for elevated levels of oxidative damage in diabetic patients.

9 Oxidative Stress and Human Disease

Oxidative stress is an inevitable accompaniment of tissue injury during human disease, for the reasons summarized in Fig. 4. For example, when phagocytes produce excess $O_2^{\bullet -}$, H_2O_2, and other species at sites of chronic inflammation, severe damage can result. This seems to happen in the inflamed joints of patients with rheumatoid arthritis and in the gut of patients with inflammatory bowel diseases, such as Crohn's disease and ulcerative colitis. Tissue injury can release metal ions from their storage sites within cells, leading to $OH^{\bullet}$ generation. This may be a particularly important mechanism in the brain, in that iron-dependent free radical reactions can occur after injury (e.g. by trauma or ischemia), spreading the injury to adjacent cells. Since oxidative stress occurs to some degree after every tissue injury, the main question to be asked in evaluating its role in human disease is not ''Can we demonstrate oxidative stress?'' but rather ''Does the oxidative stress that occurs make a significant contribution to disease activity?'' The answer to the latter question appears to be ''yes'' in at least some cases, including rheumatoid arthritis, Alzheimer's disease, diabetes, atherosclerosis, and ulcerative colitis. However, it may well be ''no'' in many others. Elucidating the precise role played by free radicals has not been easy because such species are difficult to measure, but the development of modern assay techniques is helping solve this problem.

10 Assay Methodology

The only technique that can detect free radicals directly is ESR spectroscopy, but only poorly reactive radicals can accumulate *in vivo* to levels that ESR techniques can detect. Hence, ESR studies of biological material detect fairly unreactive radicals, such as ascorbate radical. Highly reactive

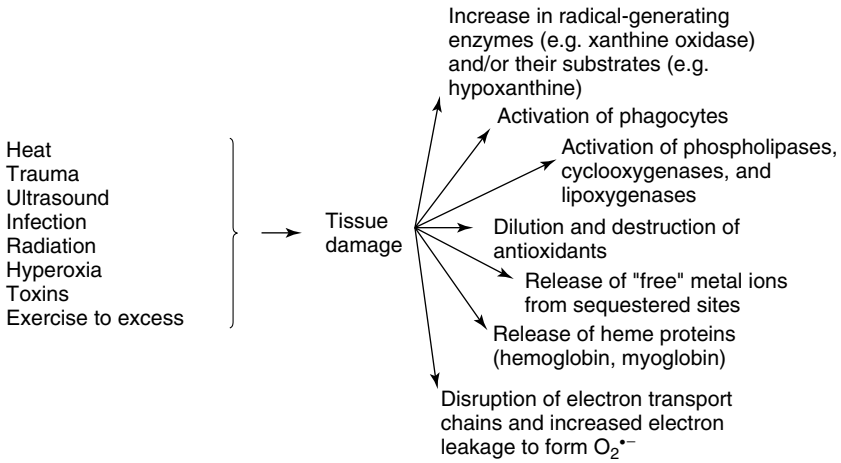

Fig. 4 How tissue damage can cause oxidative stress. [From Halliwell et al. (1992), with permission.]

radicals formed in biological systems can be identified by two general approaches. The first is trapping, and the second involves the measurement of the end products of free radical attack (Sections 10.2 and 10.3).

In trapping, the radical is allowed to react with a trap molecule to give one or more stable products, which are then measured. The most popular trapping method is spin trapping, in which the radical reacts with a "trap molecule" to form a more stable radical, which does accumulate to the level detectable by ESR. Spin traps such as α-phenyl-*tert*-butyl nitrone and 5,5-dimethylpyrroline-*N*-oxide have been useful in detecting certain free radicals *in vitro* and in whole animals, but they cannot be administered to humans.

10.1 Aromatic Hydroxylation

There are many trapping methods other than spin trapping. The technique of aromatic hydroxylation, for example, is based on the reaction of $OH^{\bullet}$ generated under physiological conditions with aromatic compounds at a diffusion-controlled rate, giving rise predominantly to hydroxylated end products. An aromatic hydroxylation assay was first applied to humans using salicylate (2-hydroxybenzoate) as a "trap" for $OH^{\bullet}$. Attack of $OH^{\bullet}$ on salicylate produces two major hydroxylated products: 2,3-dihydroxybenzoate and 2,5-dihydroxybenzoate. The latter product can be produced metabolically, whereas 2,3-dihydroxybenzoate apparently cannot. Hence, the formation of the latter product may be used to detect $OH^{\bullet}$ production *in vivo*.

Another aromatic trap for $OH^{\bullet}$ is the amino acid, phenylalanine. *In vivo*, the L-isomer of this amino acid is hydroxylated by phenylalanine hydroxylase at position 4 on the ring to give L-*p*-tyrosine. D-Phenylalanine is not recognized by this enzyme. By contrast, $OH^{\bullet}$ cannot distinguish between the two isomers: it acts on both L- and D-phenylalanine to produce a mixture of *o*-, *m*-, and *p*-tyrosines

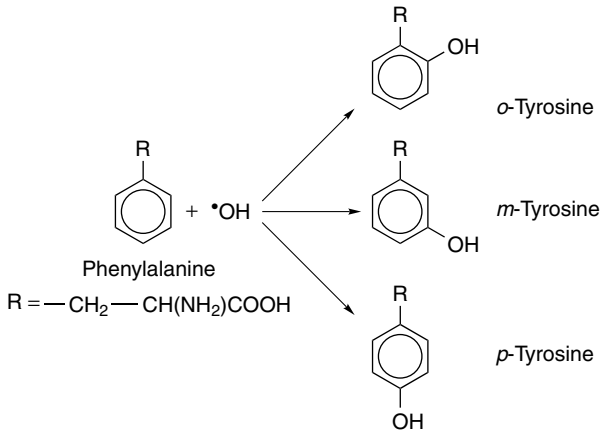

Fig. 5 Products resulting from the attack of hydroxyl radicals on the amino acid phenylalanine. Hydroxyl radicals add on to the aromatic ring to produce intermediate radicals, which are converted to hydroxylated products under physiological conditions.

(Fig. 5). Formation of these tyrosines has been used as an index of $OH^{\bullet}$ production by cells, by injured organs, and in food that has been irradiated.

10.2 Uric Acid Degradation

In humans and other primates, which lack a functional urate oxidase enzyme, uric acid is an end product of purine metabolism. (A gene resembling the urate oxidase gene of lower mammals is present in the human genome, but there is a stop codon in one of the exons.) It is widely believed that uric acid acts as an antioxidant *in vivo*. Hence, measurement of the products of attack of oxygen-derived species on uric acid is a potential marker of oxidative damage uniquely applicable to humans and to other primates. Uric acid is oxidized by several reactive oxygen species (including $OH^{\bullet}$, but not $O_2^{\bullet -}$ or H_2O_2). The major product of uric acid oxidation in all cases is allantoin, but other products formed are oxonic acid, oxaluric acid, cyanuric acid, and parabanic acid. The concentrations of all these products are increased in synovial fluid and serum from patients suffering from rheumatoid arthritis and in serum from patients with iron overload arising as a consequence of idiopathic hemochromatosis. The blood plasma of iron-overloaded hemochromatosis patients contains ''free'' iron, which can catalyze free radical reactions. By contrast, healthy subjects never contain ''free'' plasma iron or copper – it is safely bound to transport proteins.

10.3 Assays for Oxygen-derived Species – ''Fingerprint'' Assays

Instead of attempting to ''trap'' oxygen-derived species, one can sometimes implicate them as agents of tissue injury by examining the pattern of chemical change they produce upon reaction with certain biological molecules. Thus, end

products of lipid peroxidation (e.g. lipid hydroperoxides, Section 2.1) or of free radical damage to DNA (Fig. 1) and proteins can be measured. Attack on proteins of $OH^{\bullet}$ generated in site-specific metal ion–dependent reactions can generate carbonyl compounds on the proteins, and these ''protein carbonyls'' are often measured as a general index of such protein damage *in vivo*. Proteomic techniques are now being used to identify the specific proteins that are the target of oxidative damage in some human diseases.

11 Conclusion

Free radicals are a normal part of human metabolism: we cannot escape them. They can be both favorable and unfavorable, depending on the amount, the location, the chemical nature, and the levels of antioxidant defense.

Keywords

Attenuated Total Reflectance Spectroscopy
Spectroscopic sampling technique utilizing a beam of radiation entering a crystal, which undergoes total internal reflection; the beam penetrates a fraction of a wavelength beyond the reflecting surface and when a material that selectively absorbs radiation is in close contact with the reflecting surface, the beam loses energy at the wavelength where the material absorbs.

Diffuse Reflectance Spectroscopy
Spectroscopic sampling technique utilizing the energy that penetrates one or more particles and is reflected in all directions.

Fourier Transform Infrared Spectroscopy
Spectroscopic technique based on the interference of radiation between two beams to yield an interferogram, a signal produced as a function of the change of pathlength between the two beams; the two domains of distance and frequency are interconvertible by the mathematical method of Fourier transformation.

Group Frequencies
Bands that appear in an infrared spectrum, which may be assigned to particular parts of a molecule.

Infrared Mapping
Spectroscopic technique that involves recording spectra at computer controlled positions at a micro level, generating contour or axonometric plots.

Mid-infrared
Region observed in infrared spectroscopy in the range 4000 to 400 cm^{-1} showing bands due to mainly fundamental modes.

Near-infrared
Region observed in infrared spectroscopy in the range 13 000 to 4000 cm^{-1} showing bands due to overtones and combination vibrations.

Infrared spectroscopy has proved to be a powerful tool for the study of biological molecules and the application of this technique to biological problems is continually expanding, particularly with the advent of increasingly sophisticated sampling techniques associated with Fourier transform infrared spectroscopy in recent decades. Biological systems, including lipids, proteins, peptides, biomembranes, nucleic acids, animal tissue, microbial cells, and clinical samples, have all been successfully studied using infrared spectroscopy. Infrared spectroscopy has been

employed for a number of decades for the characterization of isolated biological molecules, particularly proteins and lipids. However, the last decade has seen a rapid rise in the number of studies of more complex systems, such as diseased tissues. Microscopic techniques combined with sophisticated analytical methods allow for complex samples of micron size to be investigated. A review of the sampling methods used for biological molecules is provided here. Examples of how infrared spectroscopy may be applied to various biological fields are also provided.

1 Experimental Methods

Infrared spectroscopy is a technique based on the vibrations of the atoms of a molecule. An infrared spectrum is obtained by passing infrared radiation through a sample and determining what fraction of the incident radiation is absorbed at a particular energy. The energy at which a peak in an absorption spectrum appears corresponds to the frequency of a vibration of a part of a sample molecule, allowing for straightforward identification.

1.1 Instrumentation

In the past, dispersive instrumentation was used to obtain infrared spectra, but this approach has been almost entirely superseded by Fourier transform infrared (FTIR) spectroscopy. FTIR spectroscopy is based on the idea of the interference of radiation between two beams to yield an interferogram. An interferogram is a signal produced as a function of the change of pathlength between the two beams. The two domains of distance and frequency are interconvertible by the mathematical method of Fourier transformation. The basic components of an FTIR spectrometer are shown schematically in Fig. 1. The radiation emerging from the source is passed through an interferometer to the sample before reaching a detector. Upon amplification of the signal, in which high-frequency contributions have been eliminated by a filter, the data are converted to a digital form by an analog-to-digital converter and transferred to the computer for Fourier transformation.

1.2 Transmission Methods

Transmission spectroscopy is the oldest and most basic infrared method. The method is based upon the absorption of infrared radiation at specific wavelengths as it passes through a sample. There are several different types of transmission solution cells available. Fixed pathlength sealed cells are useful for volatile liquids, but cannot be taken apart for cleaning. Semipermanent cells are demountable

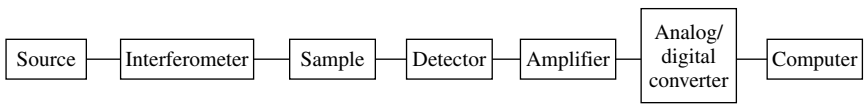

Fig. 1 Components of an FTIR spectrometer.

so that the windows can be cleaned. The spacer is usually made of polytetrafluoroethylene (PTFE or Teflon) and is available in a variety of thicknesses, allowing one cell to be used for various pathlengths. Variable pathlength cells incorporate a mechanism for continuously adjusting the pathlength and a vernier scale allows accurate adjustment. All these cell types are filled using a syringe and the syringe ports are sealed with PTFE plugs before sampling.

An important consideration in the choice of infrared cells is the type of window material. The material must be transparent to the incident infrared radiation, and normally, alkali halides are used in transmission methods. The cheapest and most widely used material is sodium chloride (NaCl). Where water is used as a solvent, particularly for biological samples, NaCl cannot be used as an infrared window material as it is very soluble in water, so calcium fluoride (CaF_2) or barium fluoride (BaF_2) are better choices. Small pathlengths (~0.010 mm) are available and help reduce the intensity of the very strong infrared modes produced in the water spectrum. The small pathlength also produces a small sample cavity, allowing samples in milligram quantities to be examined. The infrared modes of water are very intense and may overlap with the sample modes of interest, but this problem may be overcome by substituting water with deuterium oxide (D_2O). The infrared modes of D_2O occur at different frequencies to those observed for water because of the mass dependence of the vibrational frequency.

1.3 Reflectance Methods

Reflectance techniques may be used for samples that are difficult to analyze by the normal transmittance methods. Attenuated total reflectance spectroscopy (ATR) utilizes the phenomenon of total internal reflection (Fig. 2). A beam of radiation entering a crystal will undergo total internal reflection when the angle of incidence at the interface between the sample and crystal is greater than the critical angle. The critical angle is a function of the refractive indices of the two surfaces. The beam penetrates a fraction of a wavelength beyond the reflecting surface and when a material that selectively absorbs radiation is in close contact with the reflecting surface,

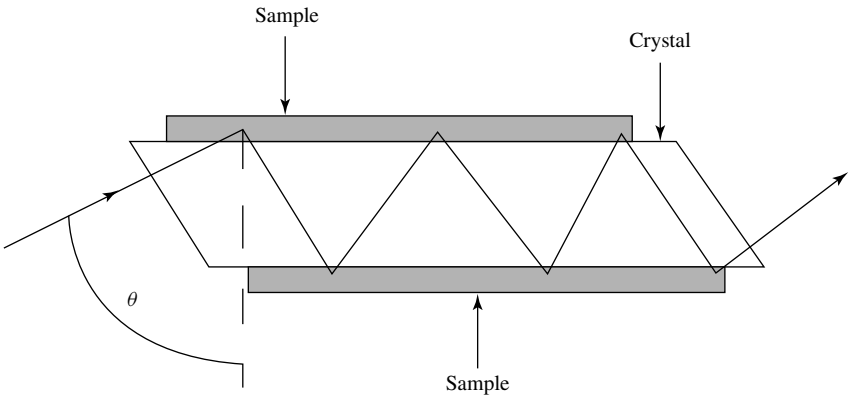

Fig. 2 Attenuated total reflectance spectroscopy.

the beam loses energy at the wavelength where the material absorbs. The resultant attenuated radiation is measured and plotted as a function of wavelength by the spectrometer and gives rise to the absorption spectral characteristics of the sample.

The depth of penetration in ATR is a function of wavelength (λ), the refractive index of the crystal and the angle of incident radiation (θ). The depth of penetration, d_p, for a nonabsorbing medium is given by the following formula:

$$d_p = \frac{\lambda/n_1}{2\pi[\sin\theta - (n_1/n_2)^2]^{1/2}} \quad (1)$$

where n_1 is the refractive index of the sample and n_2 is the refractive index of the ATR crystal. The crystals used in ATR cells are made from materials that have low solubility in water and are of very high refractive index, such as zinc selenide (ZnSe), germanium (Ge), and thallium/iodide (KRS-5). Different designs of ATR cells allow both liquid and solid samples to be examined. It is also possible to set up a flow-through ATR cell by including an inlet and outlet into the apparatus. This allows for the continuous flow of solutions through the cell and permits the spectral changes with time to be monitored. Multiple internal reflectance (MIR) and ATR are similar techniques, but MIR produces more intense spectra from multiple reflections. While a prism is usually used in ATR work, MIR uses specially shaped crystals that cause many internal reflections, typically 25 or more.

Specular reflectance occurs when the reflected angle of incident radiation equals the angle of incidence. The amount of light reflected depends on the angle of incidence, the refractive index, surface roughness, and absorption properties of the sample. For most materials, the reflected energy is only 5 to 10%, but in regions of strong absorptions, the reflected intensity is greater. The resultant data appears different from normal transmission spectra, as derivative-like bands result from the superposition of the normal extinction coefficient spectrum with the refractive index dispersion (based upon Fresnel's relations from physics). However, the reflectance spectrum can be corrected using a Kramers–Kronig transformation (or K−K transformation) and the corrected spectrum appears like the familiar transmission spectrum.

Increased pathlengths through thin coatings can be achieved using grazing angles of incidence (up to 85°). Grazing angle sampling accessories allow measurements to be made on samples over a wide range of angles of incidence. Solid samples, particularly coatings on reflective surfaces, are simply placed on a flat surface. The technique is also commonly used for liquid samples that can be poured into a Teflon trough. Oriented films on the liquid surface can be investigated using this material.

In external reflectance, the energy that penetrates one or more particles is reflected in all directions and this component is called *diffuse reflectance*. In the diffuse reflectance technique, commonly called *DRIFT*, a powdered sample is mixed with KBr powder. The DRIFT cell reflects radiation to the powder and collects the energy reflected back over a large angle. Diffusely scattered light can be collected directly from a sample or, alternatively, by using an abrasive sampling pad. DRIFT is particularly useful for sampling powders or fibers. Figure 3 shows diffuse reflectance from the surface of a sample. Kubelka and Munk developed a theory describing the diffuse reflectance process for powdered samples that relates the sample concentration to the scattered radiation intensity.

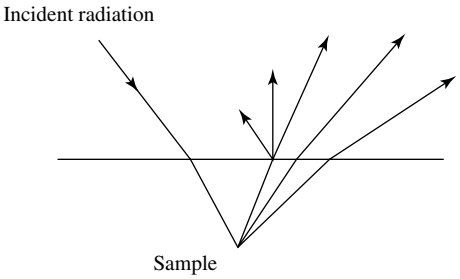

Fig. 3 Diffuse reflectance.

The Kubelka–Munk equation is

$$\frac{1-R^2}{2R} = \frac{c}{k} \tag{2}$$

where R is the absolute reflectance of the layer, c is the concentration and k is the molar absorption coefficient. An alternative relationship between the concentration and the reflected intensity is now widely used in near-infrared diffuse reflectance spectroscopy. The relationship is analogous to the Beer–Lambert Law:

$$\log\left(\frac{1}{R}\right) = k'c \tag{3}$$

where k' is a constant.

1.4 Microsampling Methods

It is possible to combine an infrared spectrometer with a microscope facility in order to study very small samples. In recent years, there have been considerable advances in FTIR microscopy with samples of the order of microns being characterized. In FTIR microscopy, the microscope sits above the FTIR sampling compartment. Infrared radiation from the spectrometer is focused onto a sample placed on a standard microscope $x-y$ stage. After passing through the sample, the infrared beam is collected by a Cassegrain objective that produces an image of the sample within the barrel of the microscope. A variable aperture is placed in this image plane. The radiation is then focused on a small area mercury cadmium telluride (MCT) detector by another Cassegrain condenser. The microscope also contains glass objectives to allow visual inspection of the sample. In addition, by switching mirrors in the optical train, the microscope can be converted from transmission mode to reflectance mode.

If a microscope facility is not available, there are other special sampling accessories available to allow examination of microgram or microliter amounts. This is accomplished using a beam condenser so that as much as possible of the beam passes through the sample. Microcells are available with volumes of around 4 μL and pathlengths up to 1 mm. A diamond anvil cell (DAC) uses two diamonds to compress a sample to a thickness suitable for measurement and increase the surface area. This technique can be used at normal atmospheric pressures, but it may also be applied to study samples under high pressures and improve the quality of the spectrum of trace samples. Alternatively, a multiple internal reflectance cell may also be used as this technique can produce stronger spectra.

Infrared imaging using FTIR microspectroscopic techniques has emerged as an effective approach to studying complex

or heterogeneous specimens. The technique can be used to produce a two- or three-dimensional picture of the properties of a sample. This is possible because, instead of reading the signal of only one detector as in conventional FTIR spectroscopy, a large number of detector elements are read during the acquisition of spectra. This is possible due to the development of focal plane array (FPA) detectors. Currently, a step-scanning approach is used, which means that the moving mirror does not move continuously during data acquisition, but waits for each detector readout to be completed before moving onto the next position. This allows thousands of interferograms to be collected simultaneously and then transformed into infrared spectra. In an FTIR imaging microspectrometer, the infrared beam from a Michelson interferometer is focused onto a sample with a reflective Cassegrain condenser. The light transmitted is collected by a Cassegrain objective and focused onto an FPA detector. The imaging process is illustrated by Fig. 4. The data are collected as interferograms with each pixel on the array having a response determined by its corresponding location on the sample. Each point of the interferogram represents a particular moving mirror position and the spectral data is obtained by performing a Fourier transform for each pixel on the array. Thus, each pixel (or spatial location) is represented by an infrared spectrum.

1.5 Temperature Studies

Variable temperature cells that are controlled to 0.1 °C in the range −180 to 250 °C can be obtained. An electrical heating system is used for temperatures above ambient, and liquid nitrogen with a heater is used for low temperatures. These cells may be used to study phase transitions and the kinetics of reactions. As well as transmission temperature cells, variable temperature ATR cells and cells for microsampling are available.

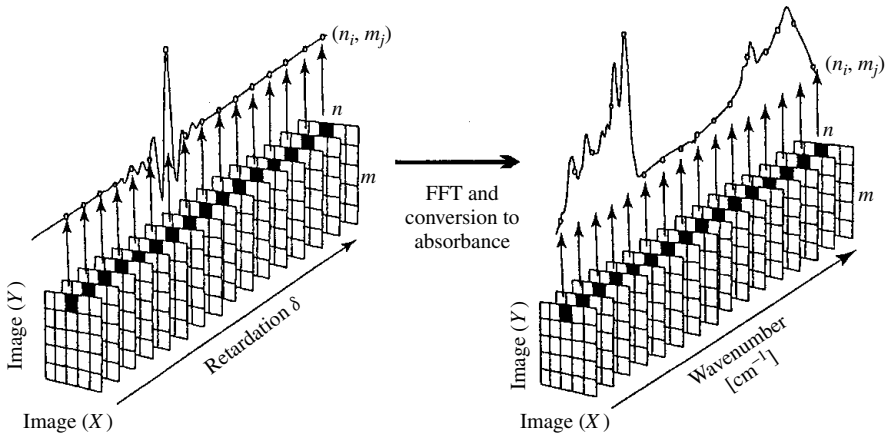

Fig. 4 FTIR imaging data set. (From Kidder, L.H., Levin, I.W., and Lewis, E.N. (1998) ''Infrared Spectroscopic Imaging Microscopy: Applications to Biological Systems,'' in: de Haseth, J.A. (Ed.) *Proceedings of the 11th International Fourier Transform Spectroscopy Conference*, American Institute of Physics, p. 148.)

2 Spectrum Interpretation

The interpretation of an infrared spectrum is simplified by the fact that the bands that appear may be assigned to particular parts of a molecule, producing what are known as group frequencies. The infrared spectrum may be divided into three regions: the far-infrared (<400 cm^{-1}), the mid-infrared (4000–400 cm^{-1}) and the near-infrared (13 000–4000 cm^{-1}). The most useful parts of an infrared spectrum for the study of biological systems are the mid- and near-infrared regions.

2.1 Mid-infrared Region

The mid-infrared spectrum can be approximately divided into four regions and the nature of a group frequency may generally be determined by the region in which it is located. These regions are defined as follows: X−H stretching region (4000–2500 cm^{-1}); triple bond region (2500–2000 cm^{-1}); double-bond region (2000–1500 cm^{-1}); and fingerprint region (1500–600 cm^{-1}).

All the fundamental vibrations in the region 4000 to 2500 cm^{-1} may be attributed to X−H stretching. O−H stretching produces a broad band that occurs in the range 3700 to 3600 cm^{-1}. It should be noted that hydrogen bonding in a molecule has a significant effect on bond frequencies, such as those observed for the O−H bond. The O−H stretching vibration in a hydrogen-bonded dimer is observed in the range 3500 to 2500 cm^{-1}, rather than the usual range 3700 to 3600 cm^{-1}. N−H stretching is usually observed between 3400 and 3300 cm^{-1}. This absorption is generally much sharper than O−H stretching and may therefore be easily differentiated. C−H stretching bands from aliphatic compounds occur in the range 3000 to 2850 cm^{-1}. They are moderately broad and show medium intensity. It is also possible to resolve asymmetrical and symmetrical C−H stretching absorptions of a CH_3 group, which usually occur at about 2965 and 2880 cm^{-1} respectively, while the corresponding absorptions for a CH_2 group occur at 2930 and 2860 cm^{-1}. If the C−H bond is adjacent to a double bond or an aromatic ring, the C−H stretching frequency increases and absorbs between 3100 and 3000 cm^{-1}.

Triple bond stretching absorptions fall in the 2500 to 2000 cm^{-1} region because of the high force constants of the bonds. C≡C bonds absorb between 2300 and 2050 cm^{-1}, while the nitrile group (C≡N) occurs between 2300 and 2200 cm^{-1}. These groups may be distinguished since C≡C stretching is normally very weak, while C≡N stretching is of medium intensity. These are the most common absorptions in this region, but some X−H stretching absorptions, where X is a more massive atom like phosphorus or silicon may be observed. These absorptions usually occur near 2400 and 2200 cm^{-1} respectively.

The principal bands in the double-bond region are due to C=C and C=O stretching. Carbonyl stretching is one of the easiest absorptions to recognize in an infrared spectrum as it is usually the most intense band in the spectrum, and depending on the type of C=O bond, occurs in the region 1830 to 1650 cm^{-1}. Metal carbonyls may absorb above 2000 cm^{-1}. C=C stretching is much weaker and occurs at around 1650 cm^{-1}, but this band is often absent for symmetry or dipole moment reasons.

C=N stretching also occurs in this region and is usually stronger. The N−H bending vibration in amines occurs between 1630 and 1500 cm^{-1} and is usually strong.

At wave numbers of values greater than 1500 cm^{-1}, it is generally possible to assign each absorption band in an infrared spectrum, but this is not so for most absorptions observed below this value. This region is referred to as the fingerprint region, since quite similar molecules give distinctly different absorption patterns at these wave numbers. It has been assumed thus far that each band in an infrared spectrum can be assigned to a particular deformation of the molecule, the movement of a group of atoms or the bending or stretching of a particular bond. This is possible for many bands, particularly the stretching vibrations of multiple bonds that are well behaved. However, certain vibrations are not so well behaved and may vary by hundreds of wave numbers, even for similar molecules. This applies to most bending and skeletal vibrations, which absorb in the 1500 to 650 cm^{-1} region, for which small steric or electronic effects in the molecule lead to large shifts. A spectrum of a molecule may have a hundred or more absorption bands present; however, there is no need to assign the vast majority. The spectrum can be regarded as a fingerprint of the molecule.

Most single bonds absorb at similar frequencies and, hence, the vibrations couple, that is, the vibrations in the skeletons of molecules are not restricted to one or two bonds, but may involve a large part of the backbone. The observed pattern will depend on the carbon skeleton, and the resulting bands will originate from the oscillation of large parts of the skeleton, or the skeleton and the attached functional groups. C−C stretching frequencies may also couple with C−H bending vibrations. The C−O stretching frequency is one of the bands that can be useful for identification purposes. If no intense band appears in the fingerprint region, one may be sure that no C−O bonds are present. The frequency is rather variable, occurring anywhere between 1400 and 1000 cm^{-1}. Aromatic rings give rise to two bands at 1600 and 1500 cm^{-1}. They are usually sharp, but are of variable intensity, and occasionally, the band at 1600 cm^{-1} splits into a doublet. Aromatic rings and alkenes give rise to other bands that are perhaps the most useful in this region. They are out-of-plane C−H bending vibrations, which occur between 1000 and 700 cm^{-1}.

The information provided by group frequencies can be summarized in what are known as *correlation tables*. Figure 5 shows a correlation table for organic molecules. The lines in the correlation table represent the regions of the spectrum where bands appear for the relevant class of molecule. Advances in computer retrieval techniques have extended the range of information available from an infrared instrument by allowing comparison of an unknown spectrum with a bank of known compounds. This was always possible in the past by manually searching libraries of spectra. Programs widely available work by hunting through stored data to match intensities and frequencies of absorption bands. The computer will then output the best fits and the names of the compounds found. There is a wide range of spectral libraries of particular interest to life scientists. For instance, libraries for the following types of samples are currently available: proteins, peptides, enzymes, sugars, carbohydrates, fatty acids, and glycerides.

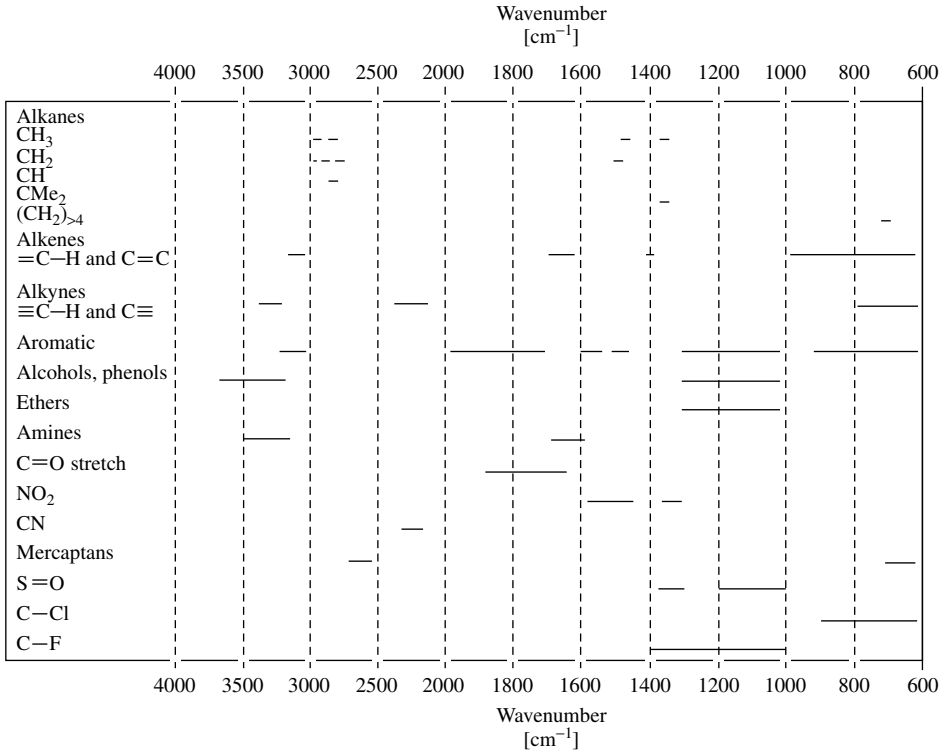

Fig. 5 Correlation table for organic molecules.

2.2 Near-infrared Region

The absorptions observed in the near-infrared region (13 000–4000 cm^{-1}) are overtones or combinations of the fundamental stretching bands that occur in the region 3000 to 1700 cm^{-1}. Overtone bands in an infrared spectrum are multiples of the fundamental absorption frequency. The energy required for the first overtone is twice the fundamental, assuming evenly spaced energy levels. Since the energy is proportional to the frequency absorbed and this is proportional to the wave number, the first overtone will appear in the spectrum at twice the wave number of the fundamental. Combination bands arise when two fundamental bands absorbing at $\overline{\nu}_1$ and $\overline{\nu}_2$ absorb energy simultaneously. The resulting band will appear at $(\overline{\nu}_1 + \overline{\nu}_2)$ wave numbers. The bands involved are usually due to C—H, N—H, O—H, P—H, or S—H stretching. Table 1 summarizes the near-infrared bands commonly found in biological molecules.

The resulting bands in the near-infrared are usually weak in intensity and the intensity generally decreases by a factor of 10 from one overtone to the next. The bands in the near-infrared are also often overlapped, making them less useful than the mid-infrared region for qualitative analysis. However, there are important differences between the near-infrared positions between functional groups and these differences can often be exploited

Tab. 1 Common near-infrared bands.

Wave number [nm]	*Assignment*
2200–2450	Combination C–H stretching
2000–2200	Combination N–H stretching, combination O–H stretching
1650–1800	First overtone C–H stretching
1400–1500	First overtone N–H stretching, first overtone O–H stretching
1300–1420	Combination C–H stretching
1100–1225	Second overtone C–H stretching
950–1100	Second overtone N–H stretching, second overtone O–H stretching
850–950	Third overtone C–H stretching
775–850	Third overtone N–H stretching

for quantitative analysis using multivariate analytical techniques.

3 Quantitative Analysis

3.1 Spectrum Manipulation

There are a number of techniques available to users of infrared spectrometers that help with both qualitative and quantitative interpretation of spectra. It is usual in quantitative infrared spectroscopy to use a baseline joining the points of lowest absorbance on the peak, preferably in reproducibly flat parts of the absorption line. The absorbance difference between the baseline and the top of the band is then used.

Noise, in a spectrum, may be diminished by smoothing. After a spectrum is smoothed, it becomes similar to the result of an experiment at a lower resolution. The features are blended into each other and the noise level decreases. A smoothing function is basically a convolution between the spectrum and a vector whose points are determined by the degree of smoothing that is applied.

A straightforward method of analysis for complex spectra is difference spectroscopy. Difference spectroscopy can be carried out by subtracting the infrared spectrum of one component of the system from the combined spectrum to leave the spectrum of the other component. If the interaction between components results in a change in the structural properties of either one or both of the components, the changes will be observed in the difference spectra. The changes may manifest themselves via the appearance of positive or negative peaks in the spectrum. Spectral subtraction may be applied to numerous applications and may be used for the interpretation of the data collected for solutions. In order to obtain the spectrum of a solution, it is necessary to record spectra of both the solution and the solvent alone. The solvent spectrum may then be subtracted from the solution spectrum. The concentration of the solvent alone is greater in the solvent in the solution and negative peaks may appear in the regions of solvent absorption. In certain circumstances, the spectrum due to the solvent may be very intense, making simple subtraction impossible. This situation can make it difficult to investigate the sample spectrum as solvent bands may overlap with the region under investigation. In such experiments, ATR provides a suitable substitute. The nature of the ATR technique produces a less intense solvent contribution to the overall infrared spectrum and so solvent spectra can be more readily subtracted from the sample spectrum of interest.

Spectra may also be differentiated. The benefits of the technique are two-fold: resolution is enhanced in the first derivative

since changes in gradient are observed; the second derivative gives a negative peak for each band and shoulder in the absorption spectrum. Differentiation can be used to resolve and locate peaks in an envelope. Sharp bands are enhanced at the expense of broad ones and this may allow selection of a peak, even when there is a broad band beneath. With modern FTIR spectrometers, it is possible to apply what is known as *Fourier derivation*. During this process, the spectrum is transformed to an interferogram. It is then multiplied by an appropriate weighting function and finally it is retransformed to give the derivative. This technique provides more sensitivity. A derivative spectrum of a peptide is illustrated in Fig. 6.

Deconvolution is the process of compensating for the intrinsic linewidths of modes in order to resolve overlapping bands. The technique yields spectra that have much narrower bands and is able to distinguish closely spaced features. The instrumental resolution is not increased, but the ability to differentiate spectral features can be significantly improved. This is illustrated by Fig. 6, which shows a broad band of a peptide before and after deconvolution has been applied. Peaks at quite close frequencies are now easily distinguished. The deconvolution technique generally involves several steps: computation of an interferogram of the sample by computing the inverse Fourier transform of the spectrum; multiplication of the interferogram

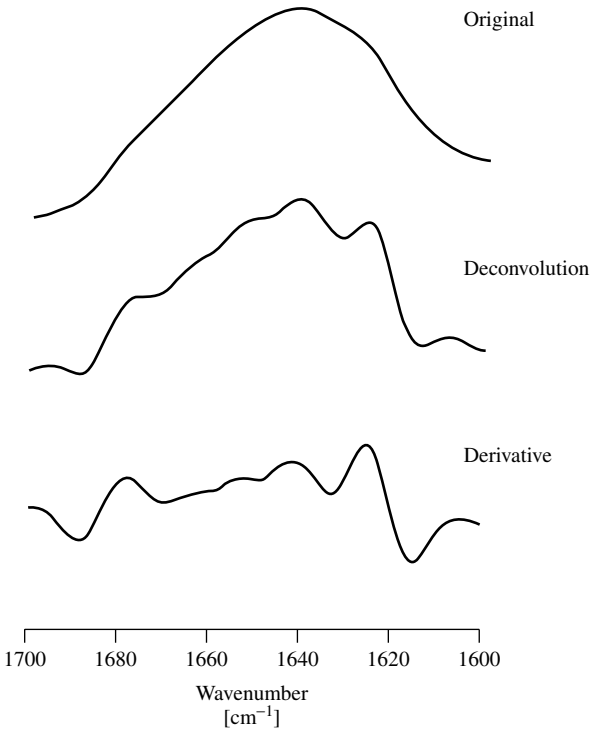

Fig. 6 Original, deconvolved, and derivative spectra of a peptide.

by a smoothing function and by a function consisting of a Gaussian–Lorentzian bandshape; and Fourier transformation of the modified interferogram. The deconvolution procedure is typically repeated iteratively for best results. At iteration, the lineshape is adjusted in an attempt to provide narrower bands without excessive distortion. There are three parameters that can be adjusted to tune the lineshape: the proportion of Gaussian and Lorentzian lineshape; the half-width of the line shape; and the narrowing function (degree of narrowing attempted on a scale 0–1).

Quantitative values for band areas of heavily overlapped bands can be achieved by using curve-fitting procedures. Many curve-fitting procedures are based on a least-squares minimization procedure. Generally, the procedure involves entering the values of the frequencies of the component bands (determined using derivatives and/or deconvolution) and then the program determines the best estimate of the parameters of the component curves. Apart from the obvious variables of peak height and width, the type of band shape needs to be considered. The class of band shape of an infrared spectrum depends on the type of sample. A choice of Gaussian, Lorentzian, or a combination of these band shapes is usually applied. Figure 7 provides an example of the curve-fitting process.

3.2 Concentration

The Beer–Lambert Law may be applied to relate light absorbance or transmittance to concentration in infrared spectroscopy. The absorbance of a solution is directly proportional to the thickness and the concentration of the sample according to the relationship:

$$A = \varepsilon c l \tag{4}$$

where A is the absorbance of the solution, c is the concentration, l the pathlength of the sample and ε is the molar absorptivity. The absorbance is equal to the difference between the logarithms of the intensity of the light entering the sample (I_0) and the intensity of the light transmitted (I) by the sample

$$A = \log_{10}\left(\frac{I_0}{I}\right) \tag{5}$$

Transmittance is defined as $T = I/I_0$, and % transmittance as $\%\ T = 100 \times T$.

The Beer–Lambert Law tells us that a plot of absorbance against concentration should be linear with a gradient of εl and pass through the origin. In theory, to analyze a solution of unknown

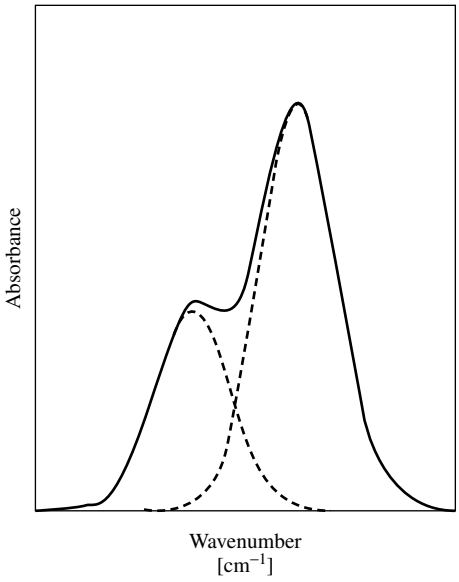

Fig. 7 Curve fitting of overlapping infrared bands.

concentration, solutions of known concentration should be prepared, a suitable peak chosen, the absorbance at this frequency measured, and a calibration graph plotted. The concentration of the compound in solution can be determined once its absorbance value is determined.

3.3 Simple Analysis

The quantitative analysis of a component in solution can be successfully carried out given that there is a suitable band in the spectrum of the component of interest. The band chosen for analysis should have a high molar absorptivity; not overlap with other peaks from other components in the mixture or solvent; be symmetrical; and give a linear calibration plot of absorbance versus concentration. Many quantitative infrared methods of analysis use the intensities of the C=O, N−H or O−H groups. The C=O stretching band is the most commonly used because it is a strong band in a spectral region relatively free of absorption by other functional groups and is not as susceptible as the O−H and N−H bands to chemical change or hydrogen bonding.

Solid mixtures can also be quantitatively analyzed using infrared spectroscopy. Solids are more susceptible to errors because of scattering problems. These analyses may be carried out with KBr discs or in mulls with an internal standard. The calibration curve is obtained by plotting the ratio of the absorbance of the analyte to that of the internal standard, against the concentration of the analyte. The absorbance of the internal standard varies linearly with the sample thickness.

3.4 Complex Analysis

The improvement in computer technology associated with spectroscopy has led to the expansion of quantitative infrared spectroscopy. The application of statistical methods to the analysis of experimental data is known as *chemometrics*. A detailed description of the subject is beyond the scope of this article, but several multivariate data analytical methods that are used for the analysis of FTIR data are summarized here, without detailing the mathematics associated with these methods. The most commonly used analytical methods in infrared spectroscopy are classical least squares (CLS); inverse least squares (ILS); partial least squares (PLS); and principal component regression (PCR). CLS (also known as *K-matrix methods*) and PLS (also known as *P-matrix methods*) are least-squares methods involving matrix operations. These methods can be limited when very complex mixtures are investigated and factor analysis methods such as PLS and PCR can be more useful. The factor analysis methods use functions to model the variance in a data set.

If it is not necessary to know the specific concentration of the species of interest, but to simply know whether the species is present or not in a complex sample, then a multivariate pattern recognition method, such as linear discriminant analysis (LDA) or artificial neural networks (ANNs), may be used to identify the spectral characteristics of the species of interest. Such methods are capable of comparing a large number of variables within a data set, such as intensity, frequency, and bandwidth. LDA and ANNs are known as *supervised methods* because *a priori* information is available about the data set. There are also unsupervised methods,

such as hierarchical clustering, which may be used to determine the components in a data set without any prior information about the data.

4 Applications

4.1 Lipids

Many lipids contain phosphorus and are classed as phospholipids. The infrared spectra of phospholipids can be divided into the spectral regions that originate from the molecular vibrations of the hydrocarbon tail, the interface region, and the head-group. The major infrared modes due to phospholipids are summarized in Table 2. The hydrocarbon tail gives rises to acyl chain modes. The most intense vibrations in the infrared spectra of lipid systems are the CH_2 stretching vibrations and these give rise to bands in the region 3100 to 2800 cm^{-1}. The CH_2 asymmetric and symmetric stretching modes at 2920 and 2851 cm^{-1} respectively, are generally the strongest bands in the spectra. The frequencies of these bands are conformation-sensitive and respond to changes of the trans/*gauche* ratio in the acyl chains. This is also the case for the vibrational modes due to the terminal CH_3 groups at 2956 cm^{-1} (asymmetric stretching) and 2873 cm^{-1} (symmetric stretching). The =C−H stretching bands due to unsaturated acyl chains are found at 3012 cm^{-1} and the bands due to methylene and methyl groups occur in the 1500 to 1350 cm^{-1} region. At around 1470 cm^{-1}, there are bands due to CH_2 bending and the number and frequency of these bands are dependent on acyl chain packing and conformation. While the asymmetric deformation modes of the CH_3 group are obscured by the scissoring bands, the symmetric deformation mode appears at 1378 cm^{-1}.

In certain phospholipid membranes that contain unsaturated acyl chains, the typical lamellar liquid crystalline phase converts to a micellar nonlamellar phase upon heating. Such a thermally induced transition involves a major structural rearrangement. Temperature studies of the infrared spectra of phospholipids provide a sensitive means of studying such transitions in lipids. Figure 8 shows the temperature dependence of the frequency of the symmetric CH_2 stretching band in the spectra of lipid membranes obtained from phosphatidylethanolamine. The increasing frequency with temperature indicates an increasing concentration of *gauche* bands

Tab. 2 Characteristic infrared bands of lipids.

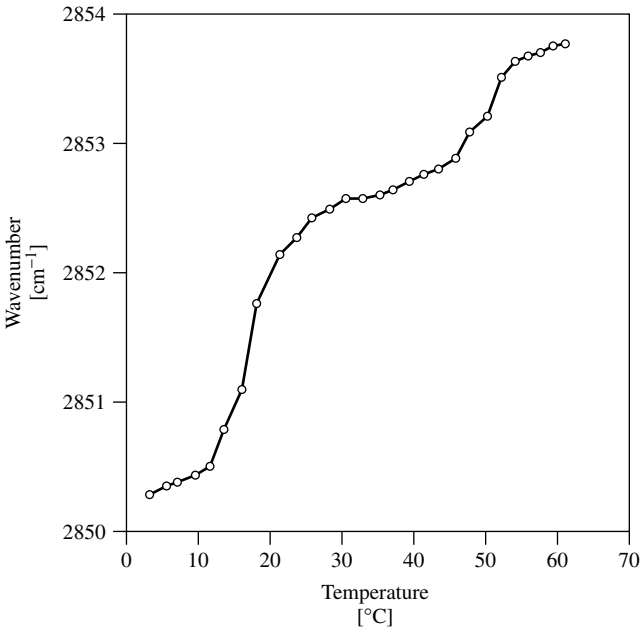

Fig. 8 Temperature dependence of the symmetric CH_2 stretching band of phosphatidylethanolamine.

in the acyl chains and this leads to the formation of the nonbilayer phase at higher temperatures. Figure 8 shows a frequency shift of about 2 cm^{-1} at 18 °C and this is associated with the gel to liquid crystal phase transition. An additional frequency shift of approximately 1 cm^{-1} at 50 °C is associated with a transition to the micellar phase. Both these transitions have been observed to be reversible.

Spectral modes arising from the headgroup and interfacial region also provide useful information. The most useful infrared bands for studying the interfacial region of lipid assemblies are the ester group vibrations, particularly the C=O stretching bands in the 1750 to 1700 cm^{-1} region. In diacyl lipids, this region consists of at least two bands originating from the two ester carbonyl groups. A band at 1742 cm^{-1} is assigned to the C=O mode of the first alkyl chain with a trans conformation in the carbon–carbon bond adjacent to the ester grouping, while the 1728-cm^{-1} C=O frequency of the second alkyl chain suggests the presence of a *gauche* band in that position. The frequency difference observed reflects the structural inequivalence of the chains, with the first alkyl chain initially extending in a direction perpendicular to the second alkyl chain and then developing a *gauche* bend in order to render the two chains parallel.

The choline, ethanolamine, and serine groups of lipids have characteristic modes. The CH_3 asymmetric stretching modes of the $(CH_3)_3N^+$ group are around 3040 cm^{-1} and are out of the range of the acyl chain CH_3 bands. The corresponding methyl bending vibrations of the choline group occur at higher frequencies, compared to those of the acyl chain methyl groups. The C−N stretching bands are found between 1040 and 800 cm^{-1}. There

are also several characteristic phosphate group vibrations: an asymmetric PO_2^- stretch around 1228 cm^{-1}; a symmetric PO_2^- stretch around 1085 cm^{-1}; P−O stretching modes in the region 900 to 800 cm^{-1}.

Adipocere is the waxy substance that can form from the tissue of dead bodies. It is known to consist mainly of fatty acids, as well as the calcium salts of certain fatty acids. During the formation of adipocere, triacylglycerols breakdown into fatty acids. Figure 9 illustrates the infrared spectrum of a sample of adipocere collected from grave soil. The spectrum shows the characteristic modes attributable to fatty acids and hydroxy fatty acids. Fatty acids show a distinctive carboxylic acid carbonyl stretching mode near 1700 cm^{-1}. Comparison with reference spectra of fatty acids indicates that the predominant fatty acid present in the sample is palmitic acid, although there is evidence that both myristic acids and stearic acid are also present in the sample. The fingerprint regions of each of the fatty acids can be used to differentiate these molecules. The carbonyl region 1800 to 1700 cm^{-1} of the sample shows several overlapping modes in the region where fatty acids are known to produce modes, supporting the observation that several fatty acids are present. The appearance of modes in the region 1600 to 1500 cm^{-1} is characteristic of calcium salts of fatty acids. These salts show carboxylate CO stretching modes near 1575 and 1540 cm^{-1}. In addition to overlapping modes due to fatty acids, there is a shoulder observed near 1740 cm^{-1}. This is a region associated with the presence of triacylglycerols. There is also a mode near 3010 cm^{-1}, which may be

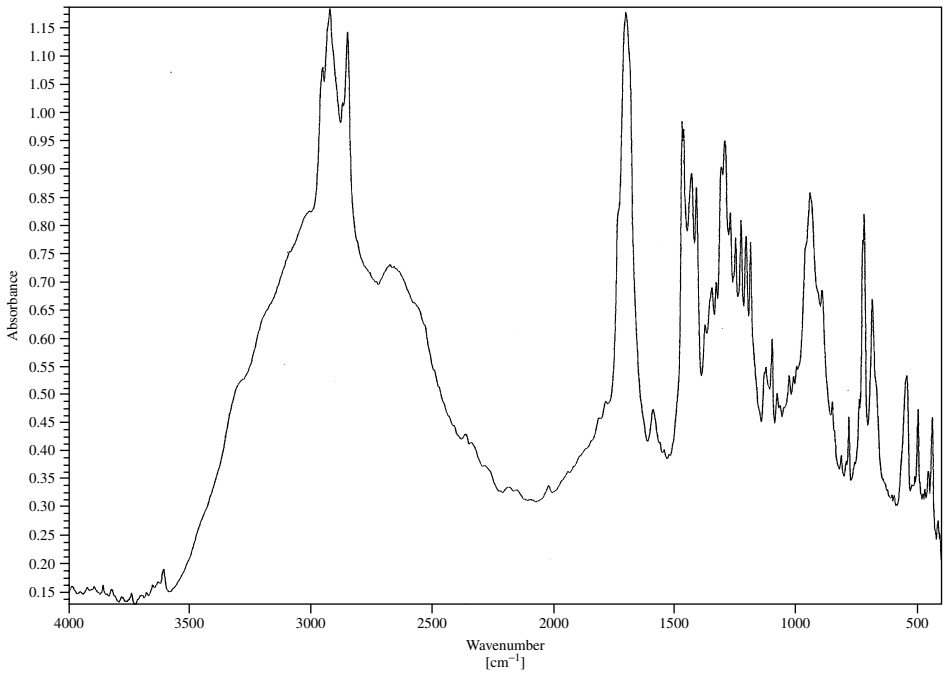

Fig. 9 Infrared spectrum of adipocere.

attributed to olefinic C−H stretching of triacylglycerols providing more evidence that triacylglycerols are still present in the adipocere. The major infrared modes of the adipocere sample are summarized in Table 3.

Quantitative infrared analysis can be carried out on blood serum to determine the relative amounts of lipid present. Triglycerides, phospholipids, and cholesteryl esters are the classes of lipid that occur in blood serum and these compounds occur naturally in concentrations that make infrared analysis attractive. These classes of compounds can be characterized by their carbonyl bands: the peak maxima appear at 1742 cm^{-1} for the triglycerides, at 1737 cm^{-1} for the phospholipid, and at 1723 cm^{-1} for the cholesteryl esters. However, the carbonyl peaks are heavily overlapped, but a least-squares method may be used to separate the components. The concentrations of these lipid components are usually in the range 0.03 to 0.3% in human blood, and standard solutions can be prepared in chloroform.

4.2 Proteins and Peptides

The infrared spectra of proteins and peptides exhibit absorption bands associated with their characteristic amide group. In-plane modes are due to C=O stretching, C−N stretching, N−H stretching, and O−C−N bending, while an out-of-plane mode is due to C−N torsion. The characteristic bands of the amide groups of protein chains are similar to the absorption bands exhibited by secondary amides in general, and are labeled *amide bands*. There are nine such bands, called amide A, amide B, and amide I-VII, in order of decreasing frequency and these bands are summarized in Table 4. Some of these bands are more useful for conformation studies than others and the amide I and amide II bands have been the most frequently used.

The amide II band mainly represents (60%) N−H bending, with some C−N stretching (40%). It is possible to split the amide II band into components depending on the secondary structure of the protein. The position of the amide II band is sensitive to deuteration, shifting from around 1550 cm^{-1} to a frequency of 1450 cm^{-1}. The amide II band of the deuterated protein overlaps with the H−O−D bending vibration, making it difficult to obtain information about the conformation of this band. However, the remainder of the amide II band at 1550 cm^{-1} may provide information about the accessibility of solvent to the peptide backbone. Hydrophobic environments or tightly ordered structures, such as α-helix or β-sheet, reduce the chance of exchange of the amide N−H proton.

The most useful infrared band for the analysis of the secondary structure of proteins in aqueous media is the amide

Tab. 4 Characteristic infrared amide bands of proteins.

Designation	*Wave number [cm^{-1}]*	*Assignment*
A	3300	N−H stretching in resonance with
B	3110	With overtone (2 × amide II)
I	1653	80% C=O stretching; 10% C−N stretching; 10% N−H bending
II	1567	60% N−H bending; 40% C−N stretching
III	1299	30% C−N stretching; 30% N−H bending; 10% C=O stretching; 10% O=C−N bending; 20% other
IV	627	40% O=C−N bending; 60% other
V	725	N−H bending
VI	600	C=O bending
VII	200	C−N torsion

I band, occurring between approximately 1700 and 1600 cm^{-1}. The amide I band represents 80% C=O stretching vibration of the amide group coupled to the in-plane N−H bending and C−N stretching modes. The exact frequency of this vibration depends on the nature of hydrogen bonding involving the C=O and N−H groups and this is determined by the particular secondary structure adopted by the protein. Proteins generally contain a variety of domains containing polypeptide fragments in different conformations. As a consequence, the observed amide I band is usually a complex composite, consisting of a number of overlapping component bands representing helices, β-structure, turns, and random structures.

In addition, the infrared contributions of the side chains of the amino acids that constitute the protein must also be considered. Amino acid side chains exhibit infrared modes that are often useful for investigating the local group in a protein. Fortunately, these contributions have been found to be small in D_2O compared to the contributions made by the amide I band. It is also important to be aware of the location of such modes as they may be confused with amide vibrations. The arginyl residue is the only residue that makes a significant contribution in the 1700 to 1600 cm^{-1} region, but even the bands at 1586 and 1608 cm^{-1} due to the arginyl residue do not contribute greatly compared to the amide I contributions. The characteristic side-chain infrared frequencies of amino acids are summarized in Table 5.

Resolution enhancement of the amide I band allows for the identification of various structures present in a protein or peptide. Derivatives and deconvolution can be used to obtain such information. However, simply measuring the peak heights of the resulting spectra does not provide an accurate measure of the proportion of the secondary structure. In Fourier deconvolved spectra, the bandshapes are distorted and the extent of this distortion depends on the widths of the component bands and the parameters used to compute the deconvolved spectra, so the resulting peak heights are complex functions of a number of parameters. Similarly, the peak heights in the derivative spectra cannot be used as a quantitative measure because they are functions of both intensities and the widths of the original bands. The best

method used for the estimation of protein secondary structure involves band-fitting the amide I band. The parameters required, the number of component bands and their positions, are obtained from the resolution enhanced spectra. The fractional areas of the fitted component bands are directly proportional to the relative proportions of structure that they represent. The percentages of helix, β-structure, and turns may be estimated by the addition of the areas of all the component bands assigned to each of these structures and expressing the sum as a fraction of the total amide I area. The assumption is made that the intrinsic absorptivities of the amide I bands corresponding to different structures are identical.

Infrared spectroscopy has been used in a large number of studies of proteins in a range of environments. Some examples of the proteins analyzed are listed in Table 6, which details the deconvolved amide I frequencies and secondary structure assignments made for a series of proteins in D_2O. These assignments are based on the fact that the secondary structures of these globular proteins have been very well characterized by X-ray crystallography. The characteristic frequencies of the secondary structures of proteins have also been estimated from normal coordinate calculations on model peptides and proteins of known structure. The frequencies are summarized in Table 7. These assignments are by no means exact and some bands may appear outside these ranges for some proteins, particularly when solvent interactions are considered.

An example of the approach to protein analysis is illustrated by Fig. 10, which shows the amide I band of the enzyme lysozyme in D_2O. The amide I band of this protein shows nine component bands and the relative areas of these components are listed in Table 8. The components may be assigned to the various types of secondary structures. The bands at 1623 and 1632 cm^{-1} are characteristic of β-structure, as is the band at 1675 cm^{-1}. The bands at 1667, 1684, and 1693 cm^{-1} occur at frequencies characteristic of turns and bends. The band at 1610 cm^{-1} is due to arginyl side-chain vibrations and

the 1640-cm^{-1} band may be assigned to random coil. The two remaining bands at 1648 and 1657 cm^{-1} are due to the presence of α-helix. Usually, in protein infrared spectra, only one component due to α-helix is observed. However, X-ray data indicates the presence of two types of helix in lysozyme: α-helix and 3-turn helix. These different helices vibrate at different frequencies and the 1657-cm^{-1} band is assigned to α-helix, while the 1648-cm^{-1} band is due to 3-turn helix. These assignments give a quantitative estimate of 48% helix, 23% β-structure, 13% turns, and 16% random coil in lysozyme.

FTIR spectroscopy is particularly useful for probing the structure of membrane proteins. The technique can be used to study the secondary structure of proteins

both in their native environment as well as after reconstitution into model membranes. Myelin basic protein (MBP) is a major protein of the nervous system and has been studied using FTIR spectroscopy in both aqueous solution and after reconstitution in myelin lipids. The amide I band of MBP in D_2O solution (deconvolved and curve-fit) is illustrated in Fig. 11. The amide band shows a small band at 1616 cm^{-1} that occurs at a frequency normally attributed to amino acid side-chain contributions. The largest component band observed at 1647 cm^{-1} is assigned to random coil and accounts for 86% of the total band area. The remaining component band at 1671 cm^{-1} is assigned to turns and bends in the protein. Table 9 lists the wave number and the fractional area of each component of the amide I band of MBP in D_2O. The FTIR spectrum of MBP protein after reconstitution in myelin, with all proteins removed from the myelin, shows that there are dramatic changes to the amide I band of MBP when the protein is complexed with myelin. The

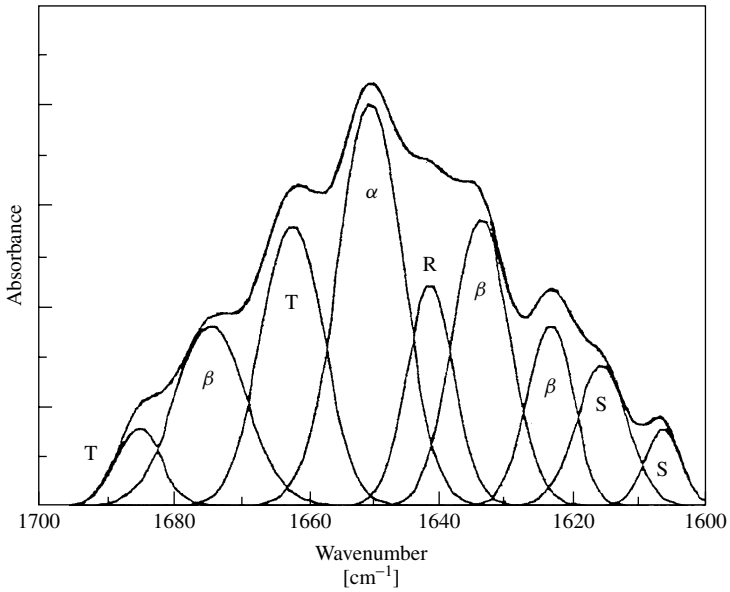

Fig. 12 Curve-fitted amide I band of MBP in myelin.

results of deconvolution and band-fitting the amide I band of MBP in myelin are shown in Fig. 12. The wave number and the fractional area of each component of the amide I band of MBP in myelin are also listed in Table 9. In Fig. 12, the two small components at 1606 and 1616 cm^{-1} occur in the frequency range attributed to side-chain contributions. The appearance of the band at 1624 cm^{-1} indicates the presence of water-bonded β-structure. Also, the component at 1634 cm^{-1} has been assigned to β-structure, with a high-frequency component due to β-structure observed at 1675 cm^{-1}. These bands contribute to 40% of the total band area. This estimation indicates that a notable amount of β-structure is formed when the results are compared to those obtained for MBP in D_2O, where no β-structure was observed. The component at 1651 cm^{-1}, contributing to 28% of the total amide I band area, has been assigned to α-helix in the protein. Thus, reconstitution of MBP in myelin produces a significant amount of α-helix in the protein in the predominantly lipid environment. Again, none of this type of structure was observed for the protein in an aqueous environment. The small component at 1642 cm^{-1} appears at a frequency normally attributed to random coil. The remainder of the components in Fig. 11 at 1663 and 1686 cm^{-1} have been assigned to turns and bends in the protein. The importance of the conditions in which biological molecules are examined in the infrared needs to be emphasized. The lipid environment more closely mimics the native environment, and thus presumably gives a far better indication of the native structure.

4.3 Nucleic Acids

Nucleic acids are vital molecules that carry the genetic code and are responsible for its expression by protein synthesis. The nucleic acids, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), may be

studied using infrared spectroscopy. The spectra of nucleic acids may be divided into the modes due to the constituent base, sugar, and phosphate groups. The bases (thymine, adenine, cytosine, guanine, and uracil) give rise to purinic and pyrimidinic vibrations in the range 1800 to 1500 cm^{-1} and these bands are sensitive markers for base pairing and base stacking effects. Bands in the region 1500 to 1250 cm^{-1} of nucleic acids are due to the vibrational coupling between a base and a sugar, and in the range 1250 to 1000 cm^{-1}, sugar–phosphate chain vibrations are observed. These bands provide information about backbone conformations. In the region 1000 to 800 cm^{-1}, sugar/sugar–phosphate vibrations are observed. The major infrared modes of nucleic acids are listed in Table 10.

4.4 Disease Diagnosis

In recent years, infrared spectroscopy has emerged as a powerful tool for characterizing tissue and disease diagnosis. High-pressure (pressure-tuning) infrared spectroscopy has been developed as a successful technique for the evaluation of malignancy in human tissues. The pressure dependence on parameters such as frequency, intensity, and band shape can provide further information about the structural changes associated with malignancy. For example, it is possible to detect cervical cancer arising from a premalignant state termed dysplasia by using infrared band differences among normal, dysplastic, and malignant cervical cells. A study of the pressure dependence of the frequencies of bands indicates that there are extensive changes in the degree of hydrogen bonding of phosphodiester groups of nucleic acids and the C–OH groups of proteins. Pressure studies also indicate changes in the degree of disorder of methylene chains of lipids in the malignant tissue. The infrared spectra of tissue samples with dysplasia demonstrate the same changes to a lesser degree than those observed for the cancer samples. Figure 13 shows the pressure dependence of the CH_2 bending mode frequency of the methylene chain of lipids for both normal and malignant tissue. Pressure increases this frequency because it induces ordering of the methylene chains in the lipid bilayers, thus increasing interchain interactions. In malignant cervical tissue, pressure induces a smaller shift in the frequency of this mode compared with normal tissue. The difference indicates that in cervical cancer, the methylene chains of

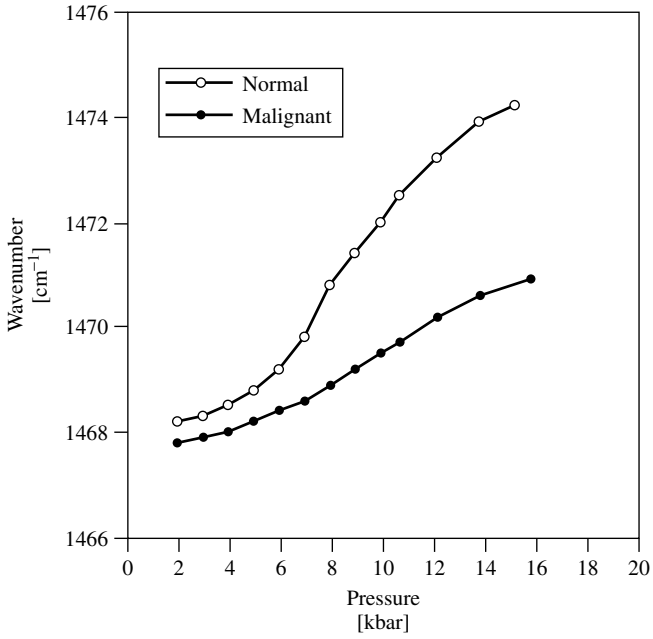

Fig. 13 Pressure dependence of CH_2 bending mode frequency of methylene chain of lipids for normal and malignant cervical tissues. (From Wong P.T.T. et al. (1991) *Proc. Natl. Acad. Sci. U.S.A.* **88**, 10988–10992.)

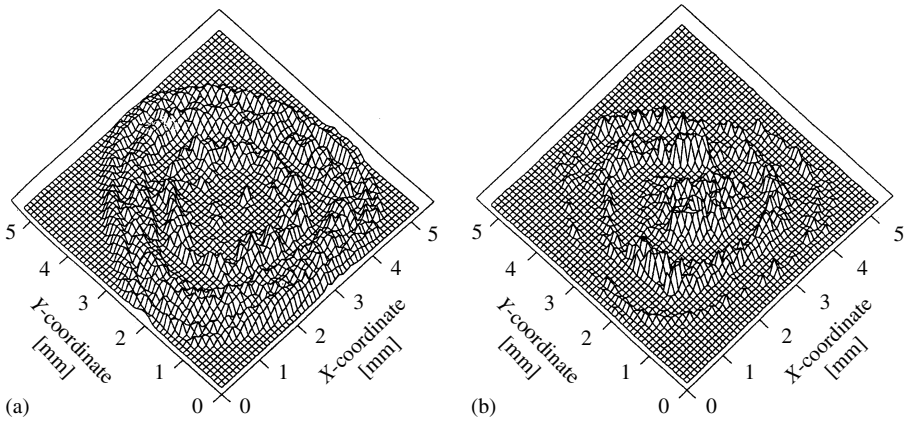

Fig. 14 Complementary functional group maps of a polished surface of sectional gallstone: (a) 875 cm^{-1} band of $CaCO_3$ and (b) 1050 cm^{-1} band of cholesterol. (From Wentrup-Byrne, E. et al. (1995) *Appl. Spectrosc.* **49**, 1028–1036.)

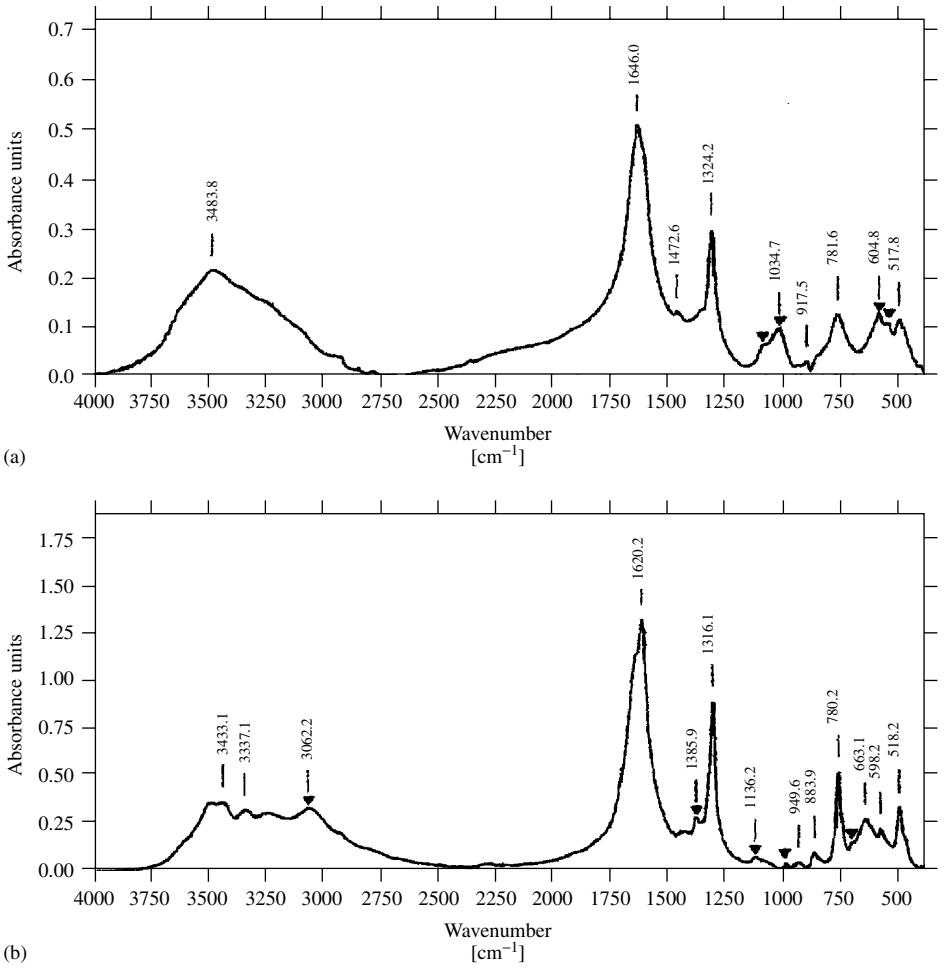

Fig. 15 Infrared spectra of kidney stones: (a) Stone mainly composed of calcium oxalate dihydrate and (b) stone mainly composed of calcium oxalate monohydrate. (From Estepa, L., Daudon, M. (1997) *Biospectroscopy* **3**, 347–369.)

lipids are more disordered than in normal cervical tissue.

Infrared mapping has the potential to be widely used to study diseased tissues. The identification of diseased regions of tissue is clearly complicated and the use of multivariate pattern recognition methods is appropriate. An example of where infrared microscopic mapping may be used to characterize disease is gallstones. Gallstone formation in the gallbladder is a common disease particularly in Western countries. The mechanism for the formation of gallstones is not thoroughly understood and knowledge of the distribution of the constituents within a stone may provide information about the mechanism of formation. A mixed stone comprised of

concentric bands has been polished and mapped. Using infrared spectroscopy, the concentric bands can be shown to consist of alternating regions of $CaCO_3$ and cholesterol. Figure 14 shows the complementary functional group maps of the polished surface of a sectioned gallstone: a map of the 875-cm^{-1} band of $CaCO_3$ and the 1050-cm^{-1} band of cholesterol.

Kidney disease is relatively common in humans and there are a number of causes of the disease. Knowledge of kidney stone composition and structure is important for establishing the etiology of the disease. FTIR spectroscopy has proved successful for the identification of the molecular structure and the crystalline composition of these complex stones. The main components of stones are calcium oxalates, calcium phosphates, and purines, but more than 85 mineral or organic compounds have been identified. There are different crystalline forms of the compounds. For example, calcium oxalate forms three crystalline forms in urine: calcium oxalate monohydrate, calcium oxalate dihydrate, and calcium oxalate trihydrate. One approach to diagnosis is to examine the form of calcium oxalate in the kidney stone. Examples of the infrared spectra produced for kidney stones of differing calcium oxalate forms are illustrated in Fig. 15. Figure 15(a) is the spectrum of a stone found to contain 95% calcium oxalate dihydrate, while Fig. 15(b) is the spectrum of a stone containing 85% calcium oxalate monohydrate. Quantitative analysis was carried out using an absorbance ratio of two peaks observed in the spectra of a binary mixture. The sample in Fig. 15(a) shows a high proportion of calcium oxalate dihydrate, which is linked to a high calcium/oxalate ratio and a high urine calcium content associated with renal hypercalciuria and hyperparathyroidism. In contrast, the predominance of calcium oxalate monohydrate for the sample in Fig. 15(b) indicates that there is a high oxalate content in the urine that is linked to primary hyperoxaluria, inflammatory bowel disease, or a high intake of oxalate-rich food.

4.5 Microbial Cells

Infrared spectroscopy has proved to be a valuable tool for characterizing and differentiating microbial cells. Given the

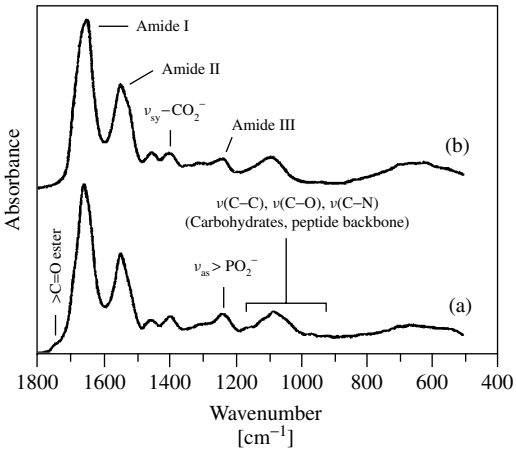

Fig. 16 Infrared spectra of *E. coli* (a) and ribonuclease A (b). (From Naumann, D. (2001) *Appl. Spectrosc. Rev.* **36**, 239–298.)

complex nature of such microorganisms, the spectra can contain a superposition of hundreds of infrared modes. However, the FTIR spectra of bacteria show modes predominantly due to the protein component. Although the cells also contain DNA and RNA structures, carbohydrates, and lipids, the various cell and membrane proteins form the major part of the cell mass. Figure 16 shows part of the infrared spectra of *Escherichia coli* and a typical protein, ribonuclease A, illustrating the similarity.

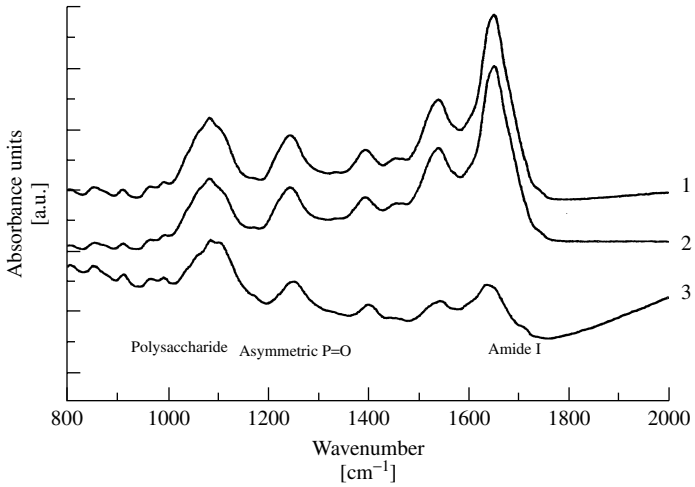

Fig. 17 Infrared spectra of an *E. coli* colony measured at center (1) and edge of colony (2) with corresponding difference spectrum (3). (From Choo-Smith, L.P. et al. (2001) *Appl. Environ. Microbiol.* **67**, 1461–1469.)

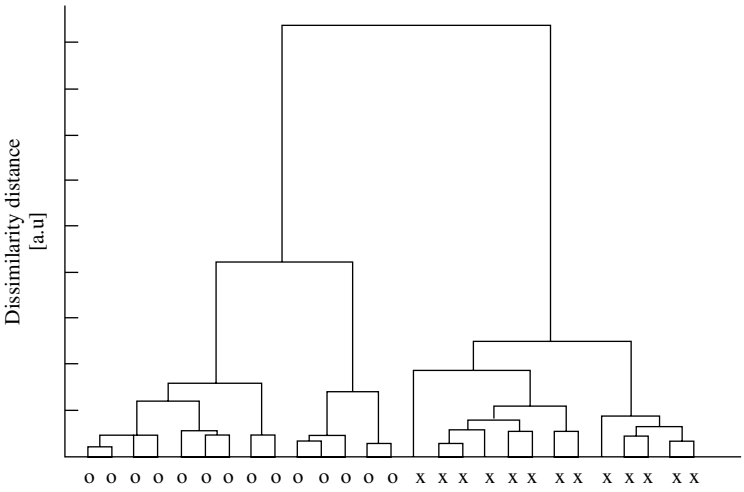

Fig. 18 Dendrogram from hierarchical clustering analysis of the infrared spectra of 7 h colonies of two *E. coli* strains. (From Choo-Smith, L.P. et al. (2001) *Appl. Environ. Microbiol.* **67**, 1461–1469.)

However, modes due to carbohydrates and lipids can also be observed in bacterial infrared spectra to a lesser extent.

FTIR spectroscopy provides a rapid method for identifying microorganisms responsible for infections. The technique has been used to monitor the biochemical heterogeneity of microcolonies of *E. coli*. By examining the individual spectra and calculating the difference spectra, it is possible to gain a better understanding of the source of the clustering. Figure 17 illustrates the infrared spectra obtained from the center and the edge of an *E. coli* colony. Despite the fact that the spectra appear very similar at first sight, difference spectra reveal variation. There are differences in the region near 1230 cm^{-1},

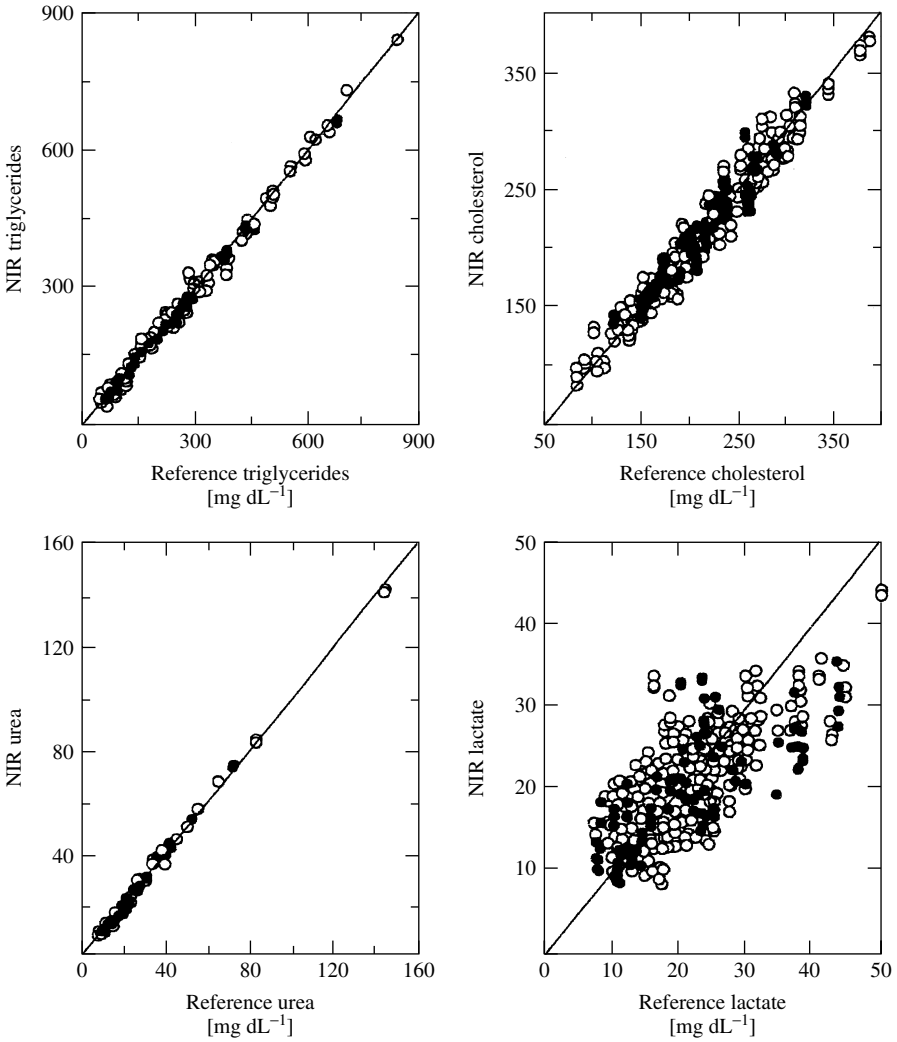

Fig. 19 Comparison of serum analyte levels determined using near-infrared spectroscopy to reference analytical results. (From Hazen, K.H. et al. (1998) *Anal. Chim. Acta* **371**, 255–267.)

which may be assigned to the phosphate double-bond asymmetric stretching vibration of the phosphodiester, free phosphate, and monoester phosphate functional groups. There are also differences observed for the protein amide I region (1670–1620 cm^{-1}), the symmetric stretching vibrations of COO^- functional groups (1400 cm^{-1}), and the carbohydrate region (1200–900 cm^{-1}). Hierarchical cluster analysis of the spectra of 7 h colonies of two *E. coli* strains were carried out and Fig. 18 illustrates the resulting dendrogram. This clearly shows the formation of two major clusters corresponding to the different strains.

4.6 Clinical Chemistry

Common infrared tests in clinical chemistry include glucose, blood, and urine analyses. The quantification of glucose in body fluids is an important aspect of clinical analysis, especially in the case of blood glucose measurements for diabetic patients. The methods of near-infrared (NIR) spectroscopy and ATR spectroscopy in the mid-infrared region lend themselves to the study of glucose in such aqueous environments, and PLS and PCR methods have been successfully applied to quantitative analysis of glucose samples. Biological fluids may also be investigated using NIR or ATR spectroscopy, both as native fluids or dry films. Figure 19 demonstrates the effectiveness of NIR spectroscopy as a technique for the quantitative analysis of native serum samples. This figure shows scatter plots that compare the concentration results obtained using NIR spectroscopy with the results obtained using standard reference clinical methods. In these experiments, the calibration procedure involved using a number of spectra and independent reference analyses and then optimizing PLS models for each constituent individually.

Keywords

Batch Culture
A closed culture system to which no major additions to nutrients are made after inoculation of the nutrient medium with the chosen microorganisms.

Continuous Culture (Chemostat)
A culture system in which the rate of addition of fresh medium balances the rate of removal of spent medium and cells, such that at steady state, the concentration of all reactants is constant.

Fed Batch Culture
A culture system to which nutrient is added at discrete time intervals or on a continuous basis, with the aim of avoiding either limitation or inhibition of O_2 owing to the nutrient.

Filamentous Fungi (Molds)
Eukaryotic microorganisms, characterized by growth at the apical tip, which form a branched network of vegetative filaments, a mycelium.

Solid Substrate Fermentation (SSF)
A low water fermentation process in which the fungus grows on or through the solid substrate, often a cereal grain or similar material.

Submerged Liquid Fermentation (SLF)
Describing liquid fermentation systems, within which the fungus is aerated and, often, mechanically agitated.

Molds (filamentous fungi) are used in the service of man to produce a wide range of valuable products, to improve feedstuffs, to carry out biotransformations, and to effect bioremediation. The technology used to cultivate and control mold activity on either solid or liquid media allows the production of high levels (kilos per cubic meter) of the desired products from selected microbial strains. Nevertheless, many problems in cultivating these microorganisms, due directly to their morphology, remain to be fully resolved. The biotechnological role of the filamentous fungi seems set to expand, with the development of effective transformation systems and increasing use of organisms such as *Aspergillus niger*, as efficient systems for the secretion of heterologous proteins. However, an understanding of the technological means of successfully cultivating these microorganisms will continue to be essential to the exploitation of their biotechnological potential.

1 Introduction

Biotechnology has been defined as ''the use of whole cells or parts derived therefrom to catalyze the formation of useful products or to treat pollutants.''

Within the broad field of biotechnology, the filamentous fungi (molds) have long occupied an important position. This diverse and metabolically versatile group of eukaryotic microorganisms is characterized by the formation of vegetative branching filaments (hyphae), which together form a mycelium. This growth pattern is a result of polarization of growth at the hyphal tip (apex).

Although most groups of molds have economically significant members, biotechnologically, the most important fungi are found within the Fungi Imperfecti, Ascomycetes, and Basidiomycetes.

Recent years have seen several major advances in our basic understanding of how the fungi work at the cellular level, including the publication of the full genome of the industrial workhorse, *A. niger* (by DSM). The publication of the genome of this organism potentially signals the start of a revolution in our exploitation of the fungi for mankind's benefit, since the relationship between genome, proteome, and cellular behavior in the fungi can now be approached on a more systematic and logical basis than hitherto. There has been great progress in the key areas of *functional genomics* (the allocation of function to each

identified gene) and *metabolic pathway engineering* (deliberate genetic alteration of a fungal strain to enhance synthesis of a desired metabolite). Advances in these areas will revolutionize our approach to understanding the physiology of the filamentous fungi.

Another recent development in our understanding of the basic function of the fungi is the discovery of ''gene silencing'' in the filamentous fungus, *Neurospora crassa*. It seems likely that both dsRNA interference and posttranscriptional gene silencing (PTGS) induced in fungi by the presence of transgenic DNA, involve sequence specific degradation of relevant messenger RNA, thus, effectively ''silencing'' the gene from which they were transcribed. This is a tremendously interesting new area with great potential for exploitation for mankind's benefit. Potentially novel methods of controlling gene activity in the fungi points the way to whole new strategies for controlling the growth of fungi in a range of environments, including medical, biotechnological, and ecological. At its simplest, this might imply the development of a completely new category of antifungal agents: given the woeful condition of our current antifungal armory and the increasing problems caused by fungi to the health of the human population, this would be immensely beneficial.

This is an exciting and rapidly developing area in the biotechnology of the fungi with revolutionary advances being made possible by our increased knowledge of fungal physiology.

1.1 Physical Characteristics of Filamentous Fungi (Molds)

The hyphal mode of growth confers a number of advantages on the filamentous fungi. These include the ability to translocate nutrients within the mycelial network, the ability to grow away from the initial growth point, such that hyphae at the edge of a colony constantly encounter fresh nutrients, and the ability to grow into solid materials (penetrative growth), thus allowing the uptake of nutrients whose availability would otherwise be restricted by diffusion.

In the growth process, fungi form branches, and branch frequency is closely related to nutrient availability.

1.2 Metabolic Activities of Filamentous Fungi

As a consequence of their mode of growth, the filamentous fungi possess a number of metabolic activities that are attractive to the biotechnologist. First among these is the synthesis and excretion of lytic enzymes (proteases, lipases, carbohydrases). Production of such hydrolytic enzymes aids fungal invasiveness. Under appropriate conditions, some fungi can secrete large quantities of proteins (50 gL^{-1} in some cases) into their environment.

The filamentous fungi are, as a group, prodigious producers of secondary metabolites. This structurally diverse group of products, formed in significant amounts during the stationary phase, includes compounds such as the penicillins and the gibberellins.

2 Development of Fungal Biotechnology

2.1 Solid Substrate Fermentation (SSF) Systems

Traditionally, molds have been used largely in the production and improvement

of foods. Natural colonization of moist grains or cereals by molds led to the discovery that certain molds could improve the flavor, texture, and nutritional value of largely carbohydrate materials.

The next steps involved control of the physicochemical conditions of the process and, later, isolation, selection, and use of particular strains. These processes, the classic examples of solid substrate fermentation (SSF) processes, are characterized by the overgrowth of the substrate, often a grain, by the fungus, which is then used as a source of enzymes to break down substrate components or for addition to other substrates. Such processes are often referred to by the Japanese term *koji*. Koji processes are still widely used in the Orient for formation of a wide range of products (Table 1). Most of these processes are now operated at the industrial scale, and many have been taken up by countries outside Asia. Tempeh, for example, in which the action of the fungi produces a material high in protein, flavorsome, and useful as a meat supplement, is produced in quantity in both Europe and the United States.

Europeans traditionally have used fungi such as *Penicillium roquefortii* and *P. camembertii* to grow on or in cheeses and to enhance flavor by production of lipases and proteases. Further use of SSF was in the industrial production of mushrooms, the most common being *Agaricus bisporus*.

All SSF systems are low water systems and generally have relatively low power inputs. Conversely, they are generally recognized as being difficult to monitor, control, and scale up. For example, O_2 transfer and the removal of CO_2 and heat can be difficult. Several SSF fermentor types are illustrated in Fig. 1.

2.2 Submerged Liquid Fermentation (SLF) Systems

Citric acid illustrates particularly well the development of the fermentation technology required for convenient formation of mold products in large quantities, at reasonable *rates* in liquid systems. Initially derived from lemon juice, citric acid was first produced industrially by a surface tray process using *A. niger*. The US firm of Pfizer used this relatively lengthy (6–12 days) labor-intensive process until 1991.

From the late 1940s, the use of the stirred-tank reactor (STR) for submerged liquid cultivation of *A. niger* resulted in citrate production processes lasting 3 to 5 days at 25 to 30 °C. A typical STR is shown in Fig. 1(d). Use of such fermentors

Tab. 1 Processes involving a koji stage.

Product	*Substrates*	*Mold involved*	*Location*
Shoyu (soy sauce)	Soy beans/wheat	*Aspergillus soyae* or *A. oryzae*	Japan (but similar products elsewhere)
Miso	Rice/barley soybeans	*A. soyae*	Japan
Sake (rice wine)	Rice	*A. oryzae*	Japan
Tempeh	Soybeans	*Rhizopus* sp. *R. oligosporus*	Indonesia

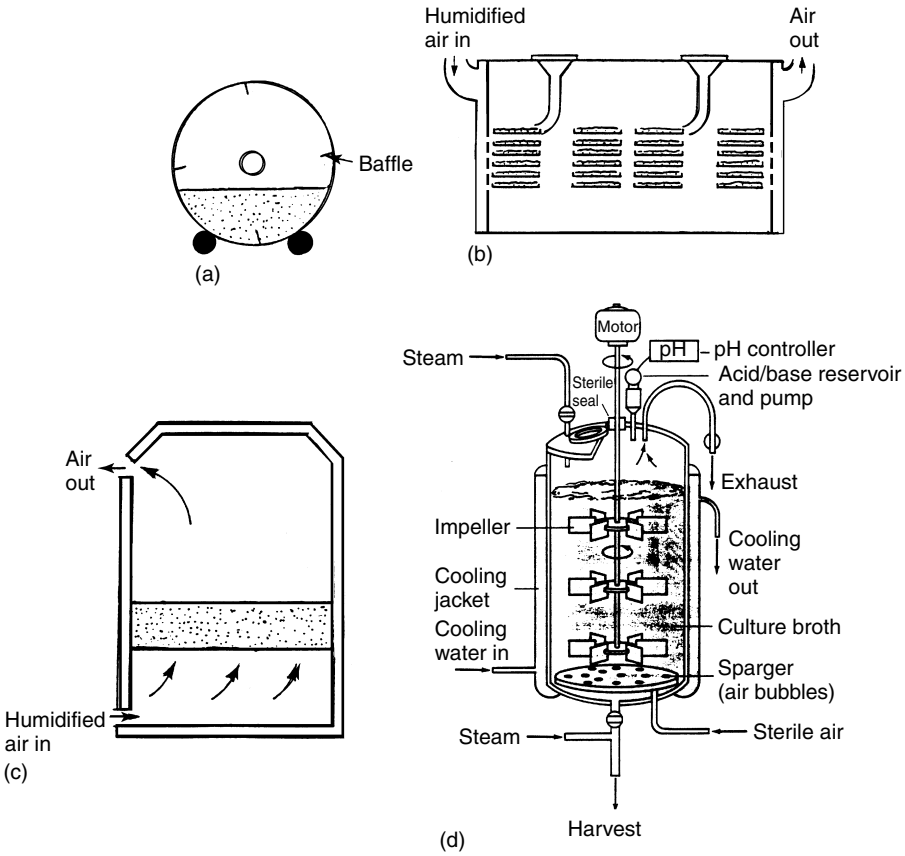

Fig. 1 Fermentor configurations showing three SSF types: (a) rotating drum, (b) tray system, and (c) formed air-flow system [from Whipps and Lumsden (1989)] and one SLF type: (d) stirred-tank bioreactor. [From Kinghorn and Turner (1992).]

allowed high oxygen transfer rates to be maintained, leading to high productivity with low manual labor needs. These fermentors were easier to monitor and control than SSF systems. The mold's physical environment could thus be more readily optimized. The STR is now the industry workhorse, a flexible reactor type used for the production of a wide range of products.

Some of the features developed in citrate fermentations are held in common with other STR mold fermentations, including the following:

- Use of highly bred (often relatively *genetically unstable*) pure cultures of production strains. (Production strains are *usually* stable these days!)
- Use of relatively crude raw materials such as molasses and corn steep liquor at the industrial scale
- Continuous aeration with sterile (filtered) air, and continuous stirring
- Maintenance of asepsis during fermentation (molds grow more slowly than bacteria and yeasts: thus any contamination by these microorganisms could lead to displacement of the fungus).

Current demand for citric acid is around 500 000 tons, though this amount is growing at 3 to 5% per year. Increasingly, the citric acid market is being concentrated in the hands of fewer, larger producers. Currently, only seven companies produce the vast bulk of citrate used.

2.2.1 Penicillins

At around the same time that submerged citrate processes developed, fermentations in STRs involving pure cultures of *Penicillium chrysogenum* for penicillin G production were also being developed. These processes are conceptually very similar to those used in citrate production. Initially, the carbon source was lactose, which permitted slow fungal growth and good excretion of the product, the secondary metabolite penicillin G. Later, fed batch processes using glucose feeds were developed. These are the current methods of production for penicillin G and V, which differ chemically only in the attached side chain (phenylacetic acid in the former, phenoxyacetic acid in the latter). Bulk penicillins G and V are increasingly used as raw materials for conversion into a wide range of semisynthetic penicillins.

Penicillins, like citrate, are mature biotechnological products produced in bulk and characterized by "survival of the fittest" with respect to producers.

2.2.2 Enzyme Production by Fermentation

Fungi are excellent sources of a wide range of lytic enzymes. Most of these are produced using the well-understood STR system described briefly in Sect. 2.2. In this area, the aspergilli are preeminent. The current world market for industrial enzymes, several of which are produced from aspergilli by SLF, is around $600 million per annum.

2.2.3 Other Liquid Fermentation Products

Table 2 lists some products of the liquid fermentation of fungi. In general, it is

Tab. 2 Some of the products of fungal biotechnology.

Organism	*Product(s)*	*Use*	*Mode of production*
Aspergillus niger	Citric acid	Acidulant	SLF (usually)
A. oryzae	Amyloglucosidase and other enzymes	Starch hydrolysis, lipolysis, proteolysis, etc.	SLF (fed batch)
Penicillium chrysogenum	Penicillins G and V	Antibacterial agents	SLF (fed batch)
Fusarium venenatum	Mycoprotein (Quorn)	Human foodstuff	SLF (continuous culture)
Gibberella fujikuroi	Gibberellins	Plant growth regulators	SLF
Tolypocladium (Beauveria)	Cyclosporin	Immunosuppressant in transplant surgery	SLF
Sclerotium glucanicum	Scleroglucan	Tertiary oil recovery; immunostimulant; antitumor agent	SLF (batch)
Agaricus campestris A. bisporus	Fruiting bodies (mushrooms)	Human foodstuff	SSF
Lentinus edodes	Fruiting body or cell extracts	Human foodstuff; immunostimulant	SLF

much easier to screen for antimicrobial activity of mold-derived compounds than for other activities. Indeed, some products such as cyclosporins were originally isolated for their antimicrobial characteristics (antifungal for cyclosporins), with their value as immunosuppressants being realized only later. It is not unreasonable to state that the use of cyclosporins have revolutionized transplant surgery.

Mucor species have been shown to accumulate large quantities of unsaturated fatty acids (e.g. linoleic). Although technically successful, SLF-based processes for production are currently not economic.

The production of mycoprotein (Quorn) by Marlow Foods (formerly ICI/RHM: Imperial Chemical Industries (now Zeneca) and Rank Hovis MacDougall) has been a considerable success. This is one of the few continuous-culture SLF processes, if not the only one, operated at the industrial scale. *Fusarium venenatum* is grown in STRs on a defined sugar–mineral salts medium, and the fungal biomass produced is harvested. By virtue of its filamentous nature, the biomass is textured, and this can be controlled or modified to simulate various meat products. The bland-tasting product readily accepts other flavors. Quorn appears to be an almost perfect foodstuff, having high protein quality, low fat content, zero cholesterol, and a reasonably high fiber content. Interest is also growing in the role of some fungal polysaccharides in modulating the immune systems of test animals. Such compounds are classed as biological response modifiers (BRMs) and include the β-glucan polysaccharides lentinan and scleroglucan. These compounds may stimulate the immune system by enhancement of macrophage activity.

3 Production Modes

3.1 Batch Culture

Although batch culture is the traditional mode of cultivation in fermentors, it is not suited to the formation of products where inhibition by substrate, product, oxygen limitation, or product precursors is a problem. Fungal citrate may be produced in batch culture.

3.2 Fed Batch Culture

In fed batch culture, the fermentation, often after an initial batch phase, is fed regularly or continuously with required nutrients or precursors. The feed is controlled to ensure that the level of the added compounds is never inhibitory to the culture, or, to avoid oxygen limitation, a rate is maintained that just balances the consumption of nutrients with oxygen consumption. Penicillins and amyloglucosidase are produced by this method, as are many other mold secondary metabolites.

3.3 Continuous Culture

The *chemostat* is the most common type of continuous-culture system encountered. Here the culture is continuously fed fresh nutrient medium, and spent medium, cells, and product are continuously drawn off. The system is not ideally suited to secondary metabolite production, but it is suitable for

biomass production, where productivities can be much higher than those in batch fermentations. This technique is also widely used on a small (lab) scale to study aspects of cellular biochemistry and physiology.

4 Problems in Cultivation of Fungi in Fermentors

Despite a long history of cultivation in both SSF and SLF systems, it is recognized that there are still some problems to be overcome. In relation to SSF systems, some of the problems have already been mentioned. In liquid systems, especially the STR, particular difficulties arise as a result of the particular morphology of the molds.

In these fermentor vessels, formation of a branched mycelium results in a rapid increase in the viscosity of the culture. The rheological character of the fermentation fluid may also change: a low viscosity Newtonian system may become highly viscous and non-Newtonian.

The general effect of this trend is to reduce mixing efficiency as well as oxygen and heat transfer in the fermentor. The result is heterogenicity within the fermentor, and, in many cases, fermentor productivity is limited.

Some producers of fungal metabolites accept these restrictions as an inevitable consequence of cultivation of filamentous fungi. Others, however, are actively seeking forms of the producing microorganisms that are less ''filamentous'' and have much shorter hyphae, to reduce the problems somewhat. It is only reasonable to state, however, that these problems are still far from being overcome.

5 Filamentous Fungi and Heterologous Protein Production

The filamentous fungi are showing particular promise in the area of production of heterologous proteins. Various fungi have been used for producing a wide range of proteins (Table 3). Initially, many of the systems were clearly aimed at examining

Tab. 3 Heterologous protein production in molds: some hosts, promoters, and products.

Host	*Promoter source*	*Origin of promoter*	*Product*
Aspergillus oryzae	Amylase	*A. oryzae*	Aspartyl protease
A. niger var. *awamori*	Glucoamylase	*A. niger*	Calf chymosin
Trichoderma reesei	Cellobiohydrolase I	*T. reesei*	Calf chymosin
A. nidulans	Alcohol dehydrogenase	*A. niger*	Human tissue plasminogen activator, human interferon, human growth hormone, human interleukin 6
Achlya bisexualis	SV40 promoter	Simian virus	Interferon

the feasibility of using fungi as expression systems for ''foreign'' genes, and these early studies often involved fungi such a *N. crassa* and *A. nidulans*. More recently, a number of companies have achieved worthwhile yields of recombinant products.

It is generally acknowledged that the filamentous fungi have a number of actual or potential advantages in this role, including the following:

1. Filamentous fungi are permissive in relation to the expression of foreign genes.
2. Some filamentous fungi can secrete into the extracellular environment copious quantities of homologous proteins. Under the correct physiological conditions, for example, *A. niger* can produce tens of grams of glucoamylase per liter of culture broth. One should not underestimate the attractions of this feature; here we have a group of organisms whose particular mode of existence requires them to possess efficient protein-exporting machinery; thus, given point 1, they would appear to be ideal secretion systems for heterologous proteins. This initial promise of copious secretion of heterologous proteins has yet to be fully realized, having proved to be rather more difficult than was first thought. Some of the reasons for this are discussed later.
3. Posttranslational patterns of processing in the filamentous fungi are much closer to those of higher eukaryotes. Since many of the proteins of commercial interest are of mammalian origin (e.g. tissue plasminogen activator (tPA), interferons); this suggests that filamentous fungi may, at first sight, be more promising hosts than well-known prokaryotic expression systems such as *Escherichia coli*. Specifically, patterns of glycosylation in fungal proteins and higher eukaryotic proteins have a degree of similarity.
4. Inclusion bodies (accumulations of denatured foreign proteins in the cytoplasm of bacteria) are not seen in fungi. Their absence is potentially advantageous, since recovery of such proteins involves cell disruption, separation, and renaturation, all of which imply increased production costs.
5. From a regulatory viewpoint, many fungi make attractive hosts for the production of proteins for food (e.g. chymosin) or therapeutic use (e.g. tPA) because the US Food and Drug Administration has given them GRAS (generally recognized as safe) status.
6. Relative to mammalian and plant cell cultures, fungal cultures are fast growing (doubling times of 3–4 h are not atypical), and the technology for cultivating molds is well characterized and readily available. Downstream processing methods are also well understood.
7. Mitotic stability of transformants is high.

Conversely, a number of potential drawbacks exist, including the following:

1. Transformation frequency is generally very low compared to transformation in bacteria and yeasts, and methods usually involve protoplast generation.
2. Filamentous fungi are a level of complexity above unicellular organisms such as bacteria and yeast, and their development of a complex three-dimensional network, with protein secretion localized to specific areas of the mycelium only, may add to the problems of operation. Despite a long industrial history, there is still a great

deal that we do not understand about the physiology, and the genetics, of industrially important fungi.

3. Many fungi produce other by-products, such as organic acids, which represent a diversion of substrate away from protein synthesis and may alter the culture pH. In addition, many fungal strains produce proteases (such as aspergillopepsin A), which could well degrade the potential product. In some cases, production of proteases can be circumvented. For example, Genencor deleted the gene for aspergillopepsin A from the production strain of *A. niger*, thus increasing the secretion of calf chymosin.
4. Because fungal cultures are highly viscous and pseudoplastic, mixing in fermentor vessels is poor. Thus, even if the conditions required to optimize heterologous protein production are known, it may not be possible to ensure that these conditions prevail throughout the fermentor vessel. If uniformly good conditions are not achieved, the overall result will be reduced productivity.
5. The relationship between copy number of the transforming gene and production of the gene product is not a simple one in some species. Such complexity may be the result of the rather random nature of the integration process.

Despite the difficulties just enumerated, there have been successes also. Notable among these is the production of calf chymosin (Genencor) and phytase (Novo Nordisk). As can be seen in Table 3, there is also considerable interest in the production of therapeutic proteins using molds. The requirements here are more rigorous than those for chymosin and phytase, which one might regard as industrial-scale products. In the case of chymosin, the aim is to maximize the yield of the product using essentially the same technology used for production of native enzymes (see Sect. 2.2). The companies involved, and more importantly, the regulatory authorities, are familiar with these, and provided evidence of the purity and authenticity of the product is available, progress toward industrial production is relatively swift. It is to be expected that the companies involved in homologous protein production will increasingly use the fungal expression technology developed over the past decade or so to improve production of many industrial enzyme processes. The GRAS status of many of the chosen host strains will be helpful in this endeavor.

Different criteria may apply with regard to the therapeutic proteins produced using fungal expression systems. Yields at the milligram- or even the microgram-per-liter level may be initially acceptable here, when the ''retail'' price is so high and society's need so great. Conversely, one might reasonably expect the path to regulatory approval to be somewhat longer, since the requirements for the demonstration of consistent purity and authenticity of products will be much more rigorous, and molds have no track record as sources of therapeutic properties.

One aspect that has become apparent is that secretion of heterologous proteins from fungi rarely reaches the levels achievable with homologous protein. For example, calf chymosin from *A. niger* reaches about $1.2\ gL^{-1}$, while *A. niger* glucoamylase can reach up to 20 to $30\ gL^{-1}$. This discrepancy has been the subject of great interest, and its resolution may go far in ensuring the success of the fungi as industrially important expression systems.

5.1 Transcription

In general, it would appear that the process of heterologous protein secretion is not restricted at the transcriptional level. (One interesting exception is the transcriptional limitation on chymosin expression in *Trichoderma reesei*). In view of the highly effective promoters in current use, this is not surprising. However, the site of integration (where the foreign DNA is introduced into the genome) may affect the expression level. This area certainly requires further study.

5.2 Translation

Despite some evidence that specific sequences upstream of the initiation code may influence translation, it is not yet clear whether protein production is markedly affected at this stage.

5.3 Posttranslational Modifications

Many eukaryotic proteins are glycosylated, and the specific pattern of glycosylation may influence protein folding (and thus activity) and aid in passage through the secretory system. If incorrectly glycosylated, they may be very rapidly degraded in mammalian systems. Unlike yeasts, fungi generally do not appear to hyperglycosylate proteins (a notable exception is expression of *T. reesei* cellulases in *A. nidulans*). Fungal patterns of protein glycosylation are closer to those of higher eukaryotes than other microorganisms.

At present, the role of glycoslylation in the secretion process is unclear and requires attention.

5.4 Gene Fusion

This strategy has improved secretion levels of a number of heterologous proteins, including chymosin and human interleukin 6. In gene fusion, the foreign gene is fused with a native gene, whose product is efficiency exported. For efficient secretion, in eukaryotes, proteins usually require an N-terminal hydrophobic secretion signal peptide; likewise, other sequences lacking the signal peptide may influence the protein's passage through the secretory system. Fusion of the calf chymosin gene with the promoter and signal peptide sequence of the glucoamylase gene led to improved production of calf chymosin in *A. nidulans*. Where product assay and screening procedures are relatively simple, a program of mutagenesis can lead to improvements in secretion levels, presumably through alterations in the sequences lacking the signal region.

5.5 Proteolysis

The problem of proteolysis induced by native proteases may also be of significance. As one might expect, most homologous proteins secreted by fungi are not degraded by native proteases, but heterologous proteins can be rapidly degraded. The deletion of the aspergillopepsin A gene has already been mentioned, but intracellular proteolysis may restrict secretion levels in many systems.

5.6 Conclusions

We selected the filamentous fungi as expression systems for foreign genes because these microorganisms are excellent

protein secretors and we believed we understood them well. What is now apparent is that we do not yet understand why certain fungi are effective protein exporters. In other words, we did not understand them as well as we thought. Fundamental research into posttranslational aspects of protein trafficking and the secretory system of fungi is required if we are to fully capitalize on the abilities of this group of microorganisms as expression systems.

6
Biotechnology of Molds in Agriculture

The filamentous fungi have a very close relationship with many plants, which can take the form of a mutually beneficial link between plant and mold (a mycorrhiza). Alternatively, many fungi are plant pathogens and can cause diseases in commercially important plant species. Other aspects of fungal activity that may impact on agricultural practice are the abilities of some fungi to attack insects, mites, nematodes, and other fungi. These latter activities indicate that fungi may have potential as biocontrol agents.

6.1
Biocontrol Using Fungi

The use of fungi to control growth of undesirable plant species (weeds), pests (e.g. insects, mites, nematodes), and other plant pathogenic fungi has a number of attractions. The first of these is the potential for specific control of the problem species by selection of a very narrow range pathogenic fungus. Other potential advantages include a possible reduction in chemical residues in or on foods or feeds, through reduced use of chemical insecticides, herbicides, pesticides, and fungicides, and the possibility of minimizing damage to the ecosystem (a consequence of the first two points listed). Thus, destruction of the problem species should not be accompanied by elimination of beneficial species or unacceptable amounts of damage to them. One final potential advantage of using living agents such as fungi in a biocontrol program is the possibility of sustained control of the pathogen or pest by permanent introduction of the biocontrol agent.

Conversely, many potential drawbacks to the use of fungi may exist, including the lack of complete control achieved by many biocontrol agents alone; the slow rate of kill of the pathogen, which may allow significant crop damage; difficulties in mass production, storage, and delivery of the infective agent itself; and reduction in efficacy due to nonideal environmental conditions. From a producer's commercial viewpoint, the possibility of persistence of the biocontrol fungus, which would reduce future sales, must also be considered. Biocontrol agents are usually more expensive to produce than chemical agents, and a greater degree of sophistication is required in their use.

6.2
Mycoinsecticides

Broadly speaking, two classes of fungi can be distinguished, biotrophic (i.e. those that can replicate only in a living host) and those capable of growth in fermentation processes. Although more than 100 fungal genera have been shown to attack insect pests, few species have actually been widely used in the field. Prominent among those that have been so used are the deuteromycete fungi

Beauveria bassiana, *Verticillium lecanii*, and *Metarhizium anisopliae*. All these fungi have been shown to produce conidia, the infective form of the organism *in vitro*. *Beauveria bassiana* is used in the former Soviet Union and in China to control pests such as Colorado potato beetle, pine caterpillars, and European corn borer.

Mycoinsecticides usually attack by direct penetration of the insect cuticle by means of enzyme action and, to a lesser extent, mechanical pressure. Since the first step in infection is the contact between the fungal spore and the insect cuticle, activity of the mycoinsecticide is heavily influenced by relative humidity and temperature. The ability of some molds to effectively secrete extracellular depolymerizing enzymes such as chitinase, proteases, and lipases is a vital feature in their ability to parasitize living insects. Thus, the potential for improvement by the use of modern molecular biological techniques clearly exists. The battery of enzymes produced corresponds to the major constituents of the insect cuticle.

In addition to enzymes, entomopathogenic fungi produce a number of toxic metabolites that may have a role in the lethal effects observed *in vivo*. *Beauveria bassiana* produces a cyclic peptide, beauvericin, and *M. anisopliae* produces a range of five related cyclic peptides, the destruxins. The synthetase gene for a very similar fungal cyclic peptide (enhiantin) has been isolated and characterized. The potential now exists for increasing the efficacy of mycoinsecticide antibiotic synthetases as probes for the isolation of synthetase genes and for the development of genetically improved strains. A better understanding of the mechanism of action and the genetics of pathogenicity should allow us to make significant improvements in these biocontrol agents by means of a molecular biological approach.

6.3 Production Technology

Ideally, the aim is a production process to turn out large numbers of conidia rapidly, cheaply, and reproducibly. Processes involved are submerged (liquid) fermentation, solid substrate, and combined.

In the West, much of the fermentation capacity is in the form of STRs, and these have been used to produce *B. bassiana* and *V. lecanii*. Many fungi, however, do not conidiate in these systems; instead, they form blastospores. These cells can be used in formulation of the mycoinsecticide, but they are considerably less stable than conidia. Surface (SSF) culture can produce large numbers of conidia, but tends to be labor-intensive. It has been successfully used in Brazil, Russia, China, Canada, and the United States for *V. lecanii* and *B. bassiana*. In many countries, it is an especially attractive, low technology, low cost local solution to local problems. Indeed, the desired fungus can be grown on nonsterile agricultural wastes. Care must be taken, however, for the danger of allergic reaction to inhalation of spores may be significant.

Combined processes usually involve STR production of mycelial cultures followed by a step that achieves induction of conidiation.

6.4 Other Fungal Biocontrol Agents

Many of the preceding comments regarding difficulties of production, formulation, application, and stability apply equally to the use of fungi in other biocontrol areas. However, fungi have been and are

being used to control weeds in many countries. Mycoherbicidal species such as *Colleotrichum gleosporoides* (active component of Collego), used to control jointvetch, and *Phytophthora palmivora* (active component of Devine) have achieved some success, and many other potential mycoherbicides are in development worldwide. Difficulties with potential mycoherbicides, such as having too broad a host range, and loss of virulence complicate development, but extensive research into the use of these agents continues. Both classical mutation and selection techniques, and recombinant DNA technology, could be used to produce stable, highly virulent strains, which defy heretofore resistant pests; these would be ideal candidates for use in integrated pest management schemes. So far, only natural isolates are in use, but as our ability to modify organisms genetically improves, progress will be made in the development of these promising nonchemical agents.

Fungi, of course, are significant plant pathogens. In the late 1980s, fungal crop diseases were estimated to cause crop damage costing several billion dollars annually in the United States alone. Legislation aimed at reducing fungicide usage inevitably means that alternatives must be found. Fortunately, many fungal species can attack and kill other species, including plant pathogenic types. Species such as *Peniophora gigantea* and *Trichoderma viride* have demonstrated antifungal activity. Again, despite considerable research, the use of such agents is still at an early stage. Before rapid progress using gene technology can be made, there must be fundamental studies into the biochemistry, genetics, and ecology of these microorganisms to improve on the ''natural'' strains in current use.

One interesting recent extension of biocontrol using fungi is the use of selected fungal species to attack ''undesirable'' plants, principally, *Papaver somniferum* (the Oriental poppy, source of opium and heroin). The misused products of this plant are a major source of social disruption, illness, and death in Western society. In a logical extension of fungal weed control systems, the use of several fungal species to attack the Oriental poppy plant was investigated. Two fungal species showed promise in attacking otherwise healthy plants.

The utilization of these lab/pilot findings in an actual field/natural context is distant, but there clearly is potential for attacking some ''weed crops'' using the fungi. Better understanding of the genetic basis of plant pathogenesis would permit a structured program to enhance the biocontrol potential of fungi against undesirable ''crop'' species. The ethical issues surrounding a program to develop a bioweapon targeting a known evil are highly complex and will potentially retard progress here more than scientific/technological challenges.

Fungal biocontrol agents have great promise as elements of integrated pest management systems, in which they may be used in conjunction with chemical agents at much reduced levels. Development of such agents, which are currently of questionable economic viability, will be driven forward by public demand, since biological control is perceived as ecologically more acceptable than chemical control.

6.4.1 Future Prospects for Fungal Biocontrol

Our increasing ability to sequence fungal genomes in a reasonable timescale and deduce the role of individual genes in

the fungal life cycle could revolutionize the use of fungi in biocontrol. Greater understanding of mechanisms of plant, insect, or nematode pathogenesis by fungi at the genetic level implies an ability to construct strains of enhanced pathogenicity. Conversely, such research potentially opens the door to manipulation of the genome of fungal species directly harmful to humans, such as *Coccidiodes immitis* or *Blastomyces dermatidis*.

6.5 Ectomycorrhizal Fungi

Ectomycorrhizas, mutually beneficial close associations between the root system of plants and a fungus (or fungi), occur in about 10% of world flora. The ectomycorrhizal fungi generally improve plant growth, increase the available area for nutrient uptake from soil, reduce the chance of infection by root pathogenic fungi, and increase tolerance to drought, toxins, and extremes of pH.

Ectomycorrhizal associations are particularly valuable in many economically important forest species from families such as Pinaceae (pine, larch, fir) Betulaceae (alder, birch), and Fagaceae (oak, chestnut, beech).

Deliberate introduction of mycorrhizal fungi into forest or nursery soils to stimulate growth has many attractions. Three methods have been used: addition of soil containing the fungi, incorporation of sporophore material, and, most reliably, inoculation of seedlings with pure cultures of vegetative mycelia. The main problem with the last approach is the difficulty of large-scale axenic cultivation of ectomycorrhizal fungi in STRs.

In addition to their widespread use in commercial forestry plantations (about 7–8 million trees annually are being ''tailored'' with specific ectomycorrhizal fungal symbionts in the United States alone), mycorrhizal fungi may also be of value in the reclamation of landfill sites. Revegetation of such sites may be hindered by presence of toxic leachates and gases, and also by absence of suitable fungal symbionts. It has been shown, however, that when fungal symbionts are present, host-plant tolerance to physical and chemical stresses improves. Ectomycorrhizal fungi may also be of help in afforestation of sites containing industrial wastes, such as anthracite waste, metallic mine tailings, and coal spoils.

6.6 Prospects

The future of ectomycorrhizal fungi in reforestation and afforestation programs looks very bright. Biotechnology is used to enhance natural processes in this instance. The remaining difficulties concerning consistent large-scale cultivation are being resolved. Further studies into the maintenance of the infectivity of ectomycorrhizal fungi after cultivation *in vitro* are still required.

7 Fungal Biotransformations

Certain fungi can carry out highly specific transformations of complex organic molecules to produce molecules of high pharmaceutical potency and high optical purity. Because of their oxidative character, fungi have great advantages in oxygen-mediated biotransformation, especially when stereospecificity is a requirement.

7.1 Steroids from Fungi

The advantages of an oxidative nature were demonstrated in the transformation of steroids by fungi such as *Curvularia, Rhizopus*, and *Penicillium raistrickii*. These fungi can carry out highly specific modifications to steroids – for example, hydroxylations, dehydrogenations, and side chain degradations – which would be extremely difficult to carry out chemically. Such modifications can alter the pharmacological activity considerably. Examples include conversion of progesterone to 11-β-OH-cortexolone by *Curvularia*.

7.2 Other Biopharmaceuticals from Fungi

The search for pharmaceutically active nonantibiotic drugs continues unceasingly, but screening for activities such as immunostimulation or immunosuppresion and antihypercholesteremia is difficult compared to antibiosis screens. It is perhaps unsurprising then that two very successful fungal products were discovered recently almost by accident. Cyclosporin A, for example, was found to be a potent immunosuppressant. However, initially, the producing organism (*Tolypocladium*) was being examined for antifungal activity and toxicity to mosquito larvae; its true potential was discovered later. The identification of the antihypercholesteremic agent mevinolin, originally isolated as an antifungal agent, was similarly serendipitous.

The discovery that cyclosporin A inhibits a cytosolic peptidyl-prolyl isomerase activity may point the way toward a more specific screen for immunosuppressive drugs based on this enzyme.

Edible fungi have long been reported to have many beneficial effects on consumption. Recent research has shown that compounds such as lentinan (from *Lentinan edodes*) and scleroglucan (from *Sclerotium glucanicum*) may be potent antitumor agents. Both compounds are high molecular weight branched glucans. Lentinan has also been shown to be capable of boosting a depressed immune system under trial conditions. Molds represent a tremendous (largely untapped) reservoir of biopharmaceuticals; the major hindrance to the biotechnological development of this resource is the current lack of directed and effective screens for desirable activities.

7.3 Combinatorial Synthesis

Although the natural synthetic versatility of the fungi is still remarkably underexploited for reasons discussed above, novel routes to libraries of potentially useful chemical entities are possible via combinatorial synthesis. In the context of fungal biotechnology, this implies taking an identified chemical species secreted/produced by a fungus, and chemically and/or enzymically creating a series of related compounds with potentially different pharmacological and chemical characteristics.

Such ''compound libraries'' are ideal for screening via high-throughput screens. Whilst the isolation of novel antiinfectious agents still dominates here, other areas of application are developing rapidly; for example, several potent inhibitors of breast cancer resistance protein (BCRP) were identified amongst chemically modified derivatives of the natural fungal BCRP inhibitor fumitremorgin. This illustrates the clear potential of such combinatorial synthesis in generating potent new compounds.

8
Fungi and Toxic Materials

White rot fungi, which have the ability to degrade a vast range of hazardous organic compounds, may be of use in systems designed to reduce the environmental impact of waste streams containing such materials or to reclaim land containing such compounds (bioremediation).

A great deal of work has been carried out on the lignin-degrading fungus *Phanerochaete chrysosporium*, and evidence suggests that lignin peroxidases are responsible for degradation of some xenobiotics.

The list of xenobiotics that can be degraded by fungi lengthens constantly. Presently included are insecticides such as DDT, lindane, and wood preservatives (e.g. pentachlorophenol), through to chlorinated biphenyls and dioxins. Despite the demonstrated potential of fungal systems in xenobiotics degradation and in the treatment of kraft pulp wastes (the toxicity of which is largely due to the presence of chlorinated phenols, catechols, and guaiacols), much work relating to how these organisms mineralize the organic materials remains to be done.

By virtue of their large surface area and the presence of charged molecules on their surfaces (polysaccharides, proteins), filamentous fungi have the ability to bind metal ions in significant amounts. Several potential uses can be made of this capacity, including the cleaning of metal-containing waste streams, the concentration of desirable metal ions such as Ni^{2+}, and the concentration of ions of uranium and thorium from process streams generated by the nuclear industry. The advantages of removing up to 90% of the metal ions from such process strains and concentrating them in the fungal biomass, which can be further processed to reduce its volume, are obvious.

9
Genetic Improvement of Fungal Strains

Once a fungus expressing a desirable trait, such as excretion of valuable metabolites or potentiality for biocontrol, has been recognized and isolated, there begins almost immediately a search to improve that characteristic. While much can be achieved in terms of metabolic or physiological control, the primary focus for strain improvement is at the genetic level.

In many fungi of commercial significance, one or more of the following methods have been adopted for strain improvement.

1. Selective screening and selection.
2. Mutagenesis, screening, and selection.
3. Use of selective ''breeding,'' sometimes by the use of the parasexual cycle, to combine desirable characteristics of two strains to give a novel genotype.
4. In the past decade or so, the ability to directly transform fungi by the introduction of a desired gene or genes has been developed.

Methods 1 and 2 have served biotechnology well. In the case of penicillin G, for example, they have contributed to increases in titer from the early isolates to current production strains of several thousandfold. They do, however, have limitations. In particular, in some systems, mutagenesis to increase metabolite synthesis may adversely affect other desired characteristics (e.g. strain vigor and fitness) that are especially important for strains used for biocontrol or as bioinoculants.

More importantly, a point of diminishing returns will be reached with respect to

the conventional methods; indeed, it has been reached for organisms such as *P. chrysogenum*.

The parasexual cycle, first recognized in *A. nidulans*, has been widely exploited to improve a range of industrial fungi by combining characteristics from related strains. The usefulness of this technique is limited by the existence of fungal incompatibility systems that restrict the occurrence of anastamosis to closely related strains. This obvious restriction on selective breeding (it narrows the genetic pool from which one can select) can sometimes be overcome by the generation of protoplasts. Such systems have been successfully applied to a range of fungal types including *T. harzianum*, *B. bassiana*, and *M. anisopliae*. Interspecies transfer is also a possibility.

At best, such methods are somewhat random even in selective breeding programs. Ideally, there is a need to specifically transfer the gene or genes responsible for the desired activity from one organism to another. The potentialities of such direct transformation have been illustrated not only in heterologous protein production but also in improvement of β-lactam-producing fungi by Lilly Research Laboratories.

Since the early studies on transformation of *A. nidulans* and *N. crassa*, the number of selective markers has steadily increased, and now a range of nutritional and dominant selective marks is available. This second group has been applied in transformation studies of many economically important metabolite- or protein-producing fungi and some plant pathogens. They include bleomycin, hygromycin, and mutant β-tubulin genes conferring benonyl resistance.

Fungal transformation commences with cell wall digestion in the presence of osmotic stabilizers, using preparations such as Novozym 234, sometimes in conjunction with other enzymes (e.g. driselase and glucuronidase). This stage may critically affect transformation frequency.

Transforming DNA has been shown to integrate into the chromosomal DNA. In *A. nidulans*, it has been possible to study direct/indirect gene replacement, and gene disruption effects.

In the work by Lilly on β-lactam producers, dominant selectable markers such as hygromycin, phleomycin, and *amid S* (acetamidase gene of *A. nidulans*) have been used in the transformation systems of *Cephalosporium acremonium* and *P. chrysogenum*. Using these systems, the investigators made progress in three distinct areas. In the first application, targeted gene disruption was used to locate and clone a β-lactam synthetic gene (*pcbAB*) in *C. acremonium*. The second application involved use of gene dosage to improve cephalosporin C titer in *C. acremonium*. Addition of one extra copy of the *cefEF* gene (which encodes for the enzyme catalyzing the rate-limiting step in cephalosporin C synthesis) led to a 15% increase in titer at the pilot scale. By comparison, mutagenesis and screening of very large numbers of derivatives of the parent strain failed to lead to the identification of any that were capable of increased productivity. This work demonstrates the great potency of the new techniques in molecular biology in overcoming identified metabolic limitations in fungi.

9.1 Pathway Engineering in *Penicillium chrysogenum*

Penicillium chrysogenum has long been used industrially to synthesize "natural" penicillins, G and V, and a family

of semisynthetic derivatives of differing antimicrobial range and potency. Cephalosporins are a related family of β-lactams traditionally synthesized by *Acremonium chrysogenum*. However, the industry would prefer to produce the cephalosporins in the more traditional and better-understood *P. chrysogenum*. Additionally, *Acremonium* undergoes a complex morphological change from (pseudo) filamentous to yeast-like, which influences the process outcome and is difficult to control.

Since the pathways of both antibiotics involve the common intermediate, isopenicillin N, introduction of a ring-expanding enzyme (expandase) would confer the potential on *Penicillium* to synthesize cephalosporin-type molecules instead of penicillins.

Thus, the final application involved biosynthetic pathway engineering, that is, the alteration of the β-lactam synthesis pathway to give a new end product, which is either an antibiotic with altered capabilities or a useful intermediate for further synthesis. This project involved the expression of the *cefE* gene of *Streptomyces clavuligerus* in *P. chrysogenum*, which led to significant synthesis of a desired enzyme (deacetoxycephalosporin C synthetase).

Taken together, these studies illustrate the tremendous capabilities of new gene technology to alter, in a planned fashion, the capabilities of existing fungal strains. Currently, such alterations require a major directed effort, with highly specific aims, and cannot realistically be justified unless they result in the improvement of an organism or the introduction of a process of great economic significance. As the technology matures, its applicability will broaden, and, undoubtedly, the bioengineering approaches discussed here will be used in many fungi of current interest.

10 Perspective

The use of molds in man's service has a long history. Conversely, their industrial exploitation can be measured in decades. These microorganisms occupy a central role in the fermentation industry and, in the near future, will continue to do so.

However, the future of fungal biotechnology will be heavily dependent on new product development and the development of new areas in which molds can be applied usefully. There are particularly promising developments in the areas of biotransformations, bioremediation using fungi, and use of filamentous fungi as systems for the expression and production of heterologous proteins. The application of the new techniques of gene transfer to filamentous fungi will leave no current application area untouched and may revolutionize our use of these techniques.

Keywords

Glucocerebroside
A glycolipid comprised of ceramide and glucose (glucosylceramide). This is the substance that accumulates in Gaucher disease.

Glucocerebrosidase
The enzyme that breaks down glucocerebroside.

Pyruvate kinase
A glycolytic enzyme.

Polymorphism
A mutation that is found in at least 1% of the genes in a population.

Pseudogene
A gene that has undergone changes so that it no longer is able to function.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.

1 Definition and History

Gaucher disease is the most common of the glycolipid storage disorders. First described in 1882 by Phillipe Charles Ernest Gaucher (1854–1918) in his doctoral thesis as an ''epithelioma of the spleen,'' it is now recognized to be the consequence of the deposition of glucosyl ceramide (glucocerebroside) in the macrophages of the body. This glycolipid is a breakdown product of globosides and gangliosides, complex glycolipids that are constituents of the normal cell membrane. Normally, the enzyme glucocerebrosidase cleaves glucocerebroside into glucose and ceramide, but in Gaucher disease, a deficiency of glucocerebrosidase leads to accumulation of glucosyl ceramide.

Clinically, three major types of Gaucher disease have been delineated on the basis of the absence (type 1) or presence and severity (types 2 and 3) of primary central nervous system involvement. Type 1 disease is sometimes designated as the ''adult'' form of the disease, but since type 1 disease often becomes apparent in early childhood, this is a misleading term. Within each type, even within the same ethnic groups, the phenotypes and genotypes can be markedly heterogenous.

2 The Glucocerebrosidase Gene

The glucocerebrosidase gene (*GBA*) is located on chromosome 1 at q21. It is approximately 7 kb in length and contains 11 exons. It is in a region that contains several genes that are of medical interest, including the red cell and liver pyruvate kinase gene (*PKLR*), the thrombospondin gene, and the metaxin gene. A 5-kb pseudogene is located about 16 kb downstream from the glucocerebrosidase gene (Fig. 1). The pseudogene has maintained a high degree of homology with the functional gene. Although it is transcribed, an unusual property for a pseudogene to possess, it does not contain a long open reading frame and has a 55-bp deletion from what was once the coding region. Alu sequences that have been inserted into introns give the functional gene greater length than the pseudogene. The putative TATA- and CAAT-like boxes of the promoter have been identified about 260 bp upstream from the upstream ATG start codon.

The cDNA is about 2 kb in length. There are two ATGs at the 5′ end and both are utilized in translation. The relative importance or function of these two start sites is unknown. Messenger RNA of several different lengths has been detected, probably because of the existence of alternative polyadenylation sites, alternative splicing, or presence of pseudogene mRNA.

3 Polymorphisms and Deficiency Mutations

Eleven polymorphic sites are known to exist in the introns and flanking regions of the acid ß-glucosidase gene, but somewhat surprisingly only 4 haplotypes have been found. These sites and the haplotypes that have been identified so far are summarized in Table 1. A considerable number of point mutations that cause glucocerebrosidase deficiency, and hence Gaucher disease, have been identified. Some of the more common of these are summarized in Table 2. An up-to-date list can be found

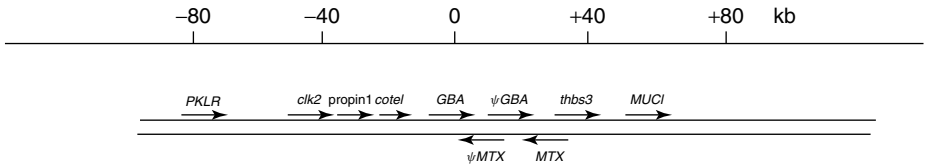

Fig. 1 A schematic representation of the genes surrounding the glucocerebrosidase (*GBA*) gene. The arrows show the direction of transcription.

at http://www.tau.ac.il/~racheli/genedis/gaucher/gaucher.html.

Some genes with the 1448C mutation have been found to contain other mutations, each corresponding to the sequence of the pseudogene. In some cases, this type of mutation has been shown to represent a crossover between the functional gene and the pseudogene, with loss of genetic material between the two. In other cases, the mechanism by which the abnormal mRNA has been formed has not been elucidated, and the alleles have merely been referred to as *complex alleles, pseudopattern, or rec* (for recombinant). The mechanism by which these are formed may all be identical to that demonstrated to occur in the XOVR mutation or may represent the result of gene conversion events.

Some of the mutations are relatively mild in their phenotypic effect and have been associated only with type 1 disease. Others are more severe and are also observed in type 2 or type 3 neuronopathic disease. In some instances, the number of cases that have been observed is so limited that the severity of the mutation is not known. A severity score has been devised that allows one to express the clinical severity of patients with Gaucher disease. As shown in Fig. 2, patients who are homozygous for the 1226G mutation tend to have relatively mild disease with a late onset, while patients who also carry one of the more drastic mutations have more severe disease with early onset. Homozygotes for the c.1342 G→C (D409H) present a unique clinical picture that includes calcification of cardiac valves and corneal opacities. The mechanism of this unusual disease phenotype, observed only with this mutation, is unknown.

4 Population Genetics

Of the many mutations that have now been documented, only three appear to approach polymorphic frequencies. The

1263–1317 del	5879–5933[c] del		?	Severe	Uncommon

Recombination events that cause Gaucher disease			
Location of crossover event(s)[d]		***Effect***	***Population frequency***
>1343 <1388	>5957 <6272[e]	Severe	Uncommon
>1317 <1343	>5932 <5957	Severe	Uncommon
>1343 <1388	>5957 <6272	Severe	Uncommon

[a] Nucleotide or amino acid position.
[b] Common = high frequency in at least one population; Uncommon = found in a number of unrelated patients.
[c] Pseudogene sequence.
[d] Only approximate ranges can be given, since the pseudogene and functional gene contain long identical sequences.
[e] Physical fusion with loss of intergenic segment.

most common is the A→G transition, at nt 1226, which produces a protein with an Asn→Ser substitution at amino acid 370 of the mature protein. It is present in about 6% of the Ashkenazi Jewish population. This mutation is the principal cause of the high incidence of Gaucher disease in this ethnic group. An insertion of a guanine at nt 84 of the cDNA is the second common Jewish mutation. It is found in approximately 0.6% of the Jewish population. Because it produces a frameshift even before the amino terminus of the mature protein, this drastic mutation produces no enzyme protein. A T→C transition at nt 1448, producing a Leu→Pro substitution at amino acid 444 of the mature protein, is present at a relatively high frequency in the Norrbottnian population of Northern Sweden. The same mutation also occurs in other populations at low frequencies. It is

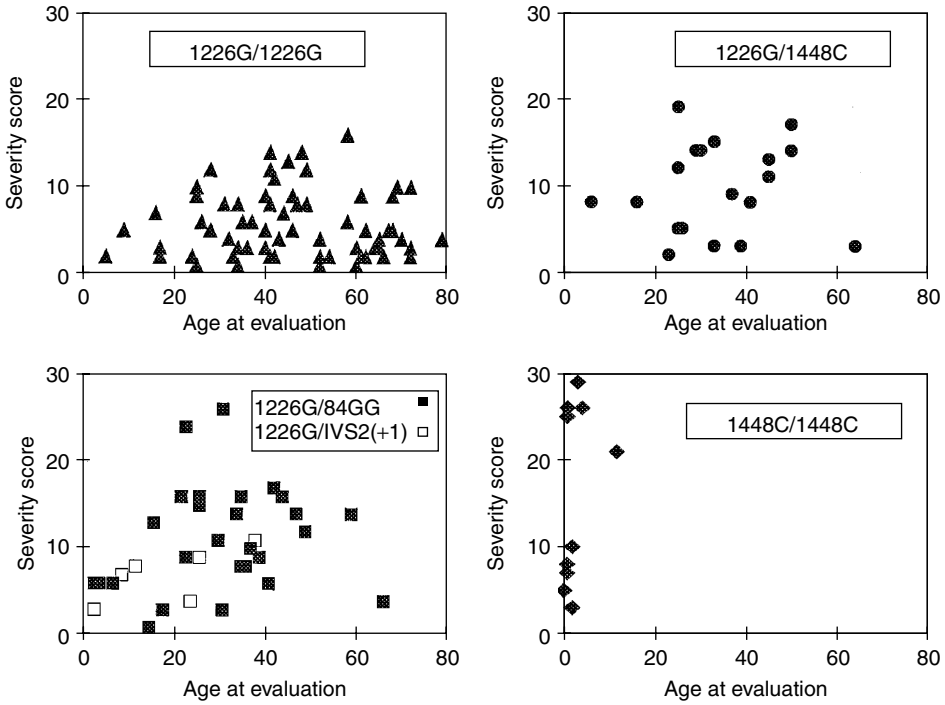

Fig. 2 The relationship between the age at the time of evaluation and the severity score of patients with four different Gaucher disease genotypes. The most severe disease is seen in the 1448C homozygotes, while many of the patients who were homozygous for the 1226G mutation are elderly and have very mild disease.

noteworthy that the homologous position in the pseudogene is occupied by a C, just as in the Gaucher disease–producing mutation.

The maintenance of a high degree of linkage disequilibrium between the 1226G mutation, common in the Jewish population, and the nearby *PKLR* gene implies that the 1226G mutation arose relatively recently, and estimates of its time of origin range from several hundred to several thousand years ago.

2-DE Differential Protein Expression Analysis
The comparison of protein expression levels between two or more biological states by 2-DE and postseparation protein visualization and quantitation.

Fluorescence 2D-difference Gel Electrophoresis (2D-DIGE)
A 2-DE-based differential protein expression analysis technique involving the derivatization of multiple protein samples with spectrally distinct fluorescent dyes, allowing separation and quantitation within the same 2-DE gel.

NHS-Cy2/Cy3/Cy5 Cyanine Dyes
A charge- and size-matched set of spectrally distinct fluorescent cyanine dye derivatives used in 2D-DIGE for the differential labeling of primary amine groups in multiple protein samples.

Fluorescence two-dimensional difference gel electrophoresis (2D-DIGE) is a recently developed 2D-gel-based proteomics technique that can be applied to provide a sensitive, rapid, and quantitative analysis of differential protein expression between two or more biological samples. This technique utilizes chemical derivatives of spectrally distinct fluorescent cyanine dyes (Cy2, Cy3, and Cy5) to covalently label different samples prior to mixing and separation on the same 2-DE gels. This differential labeling and mixing of samples helps avoid the gel-to-gel variation inherent in conventional 2-DE-based expression profiling and reduces the number of gels that need to be run. Since the technique is also compatible with downstream identification of protein spots from gels by mass spectroscopy, it is particularly useful for reproducible, high-throughput proteomics.

1 Principles

1.1 Proteomics by 2-DE Differential Protein Expression Analysis

Proteomics is the study of biological processes or disease states in terms of qualitative and quantitative changes in proteins. This includes the monitoring of changes in protein expression, activity, cellular or tissue distribution, modification, and interactions with other proteins, biomolecules, or drugs. Of these, the ability to determine significant alterations in protein expression that correlate with disease or occur consequent to induced changes in cells is fundamental to the exploitation of proteomics.

Historically, the most commonly applied method for this differential protein expression analysis is two-dimensional gel electrophoresis (2-DE), and despite its inherent detection and resolution limits (see Sect. 2), it remains the best and the most amenable technique for the global analysis of protein expression. This technique involves the physical separation of proteins

from biological samples using denaturing polyacrylamide gel electrophoresis (PAGE). Separation in the first dimension, or isoelectric focusing (IEF), is based upon the native charge of each protein. Proteins will migrate through a polyacrylamide gel with an applied pH gradient and electric field until they ''focus'' at the pH at which they are neutrally charged, their isoelectric point (pI). The first dimension is then applied to a second dimension polyacrylamide gel that is used to further resolve the proteins according to their relative molecular weight when complexed with the anionic detergent SDS, a technique known as sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The separation works on the principle that SDS binds to proteins with a constant stoichiometry, such that smaller SDS–protein complexes can migrate faster through the molecular ''sieve'' created by the polyacrylamide compared to the larger ones. Separated protein mixtures are then visualized directly in 2-DE gels, or on nitrocellulose or polyvinylidene difluoride (PVDF) membranes following electrophoretic transfer. Visualization can be achieved using various protein staining methods, immunodetection with specific antibodies, or by radioactive detection, when samples are first metabolically labeled with radioisotopes. Relative protein expression levels are then deduced by quantitation of protein staining (or labeling) using scanning densitometry or other imaging techniques. Significant differences in expression are then determined by comparing values across the different sample sets after computational superimposition of gel images and matching of protein spots or gel features.

In recent years, 2-DE expression profiling has been linked with the downstream identification of differentially expressed proteins directly from excised gel pieces. The analytical methods applied mainly rely on identification of peptides extracted from gel pieces following site-specific proteolysis. While it is possible to identify extracted peptides by direct Edman sequencing, mass spectrometric methods have come to the fore as the most sensitive and rapid means of identifying low-level proteins. The two main mass spectrometry (MS) techniques applied to protein identification from gels are peptide mass fingerprinting by matrix-assisted laser-desorption ionization mass spectrometry (MALDI-MS) linked to peptide mass database searching, and electrospray ionization-collision-induced dissociation tandem mass spectrometry (ESI-CID MS/MS) with fragment ion or sequence tag database searching. ESI-CID MS/MS usually incorporates front-end separation of the peptide digest by reverse-phase liquid chromatography, a technique abbreviated to LC-MS/MS. Since LC-MS/MS analysis provides sequence information on the sample, it allows the unambiguous identification of proteins as long as they are already represented in a database. This combination of 2-DE and MS provides the major driving force for high-throughput differential protein expression analysis in proteomics.

1.2 Methods of Protein Visualization: Problems and Pitfalls

Radiolabeling is the most sensitive method for protein visualization in 2-DE-based expression analysis and undoubtedly has the broadest dynamic range of all detection methods. Metabolic radiolabeling also has the advantage that it can provide temporal as well as quantitative information on protein synthesis, turnover, and posttranslational modifications. Despite

these advantages, metabolic radiolabeling is both hazardous and expensive and can result in unwanted DNA fragmentation, cell growth arrest, and even cellular apoptosis. For these reasons, many researchers have moved away from metabolic radiolabeling as a technique for expression profiling, and instead rely more on conventional protein staining strategies.

Over the years, many different kinds of noncovalent protein staining methods have been employed for visualization and quantitation of proteins in 2-DE gels or on membranes following electroblotting. The majority of these staining methods rely on dyes that interact directly with proteins, for example, Coomassie Brilliant Blue (CBB) R-250, colloidal CBB G-250, amido black, and the fluorescent dyes SYPRO Ruby and SYPRO Rose. Other sensitive direct staining methods include acidic silver nitrate and alkaline silver diamine staining of gels and colloidal gold staining of proteins electroblotted onto membranes. Indirect staining can also be achieved using fluorescent dyes such as Nile Red, SYPRO Orange, SYPRO Red, and SYPRO Tangerine, which interact with the SDS micelle around the protein. Alternatively, reverse staining of gels with zinc-imidazole, or potassium, copper, or zinc chloride–staining methods creates a semiopaque gel background, with proteins detected as transparent spots when viewed with appropriate back illumination.

Staining with CBB and silver are the most commonly used methods for comparative quantitation in 2-DE gels, and CBB staining still remains one of the most reliable and heavily used detection methods owing to its compatibility with downstream Edman sequencing and mass spectrometry. Although conventional CBB staining is relatively insensitive, colloidal CBB staining is capable of detecting as little as 20 ng of protein. Silver staining, although sensitive (2–4 ng), is not particularly compatible with subsequent microchemical analysis. This is largely due to the inclusion of aldehyde-based fixatives in staining procedures. These fixatives not only reduce the recovery of peptides from in-gel protein digests, but also result in protein alkylation that complicates Edman sequencing and peptide mass profiling by MALDI-MS. A solution to this problem has been the development of more MS-compatible silver-staining techniques that omit aldehydes and only superficially stain proteins at the gel surface. However, these modified staining protocols have decreased sensitivity and give higher levels of background staining. In addition, reduction of spectral intensity and inferior sequence coverage in peptide mass fingerprinting experiments have been reported using these protocols, although silver-destaining methods can be employed to improve mass spectrometric analysis.

The use of CBB, silver, and other nonfluorescent staining methods in differential protein expression analysis also suffers from two other major drawbacks. Firstly, these methods have relatively small linear dynamic ranges of detection, and thus are not ideal for the proteomic analysis of complex biological samples in which the dynamic range of protein abundance can be up to eight orders of magnitude. Secondly, staining by these methods can vary quite considerably from protein to protein and from gel to gel. This is particularly the case for silver staining in which temperature, the critical timing of the different steps in the staining protocols, and the lack of a staining end-point leads to appreciable variation in staining intensity from gel to gel.

1.3 Fluorescence Detection in 2-DE Expression Profiling

Improvements to proteomic protein visualization are now largely focused on fluorescence detection. Since measurement of light emission is intrinsically more sensitive than measurement of light absorbance, fluorescent protein stains have the potential to allow detection of very low levels of protein. In addition, fluorescent stains offer a much broader linear dynamic range of detection, making them more suitable for expression profiling of cell and tissue samples. Recently, the commercially available noncovalent fluorescent SYPRO stains from Molecular Probes, Inc. have been used for high sensitivity–protein visualization in gels and on membranes.

Of these stains, the ruthenium-based metal chelate fluorescent stain SYPRO Ruby appears to be the most sensitive for in-gel protein visualization. It is reported to detect down to 2 ng of protein (as good as the best silver-staining methods), and is an end-point stain, making it impossible to overstain gels. SYPRO Ruby binds to proteins in a manner similar to CBB, but has a linear dynamic range extending over three orders of magnitude, better than any nonfluorescent staining strategy. In addition, SYPRO Ruby staining has been reported to be compatible with downstream identification of proteins by MALDI-MS peptide mass profiling. These properties suggest that SYPRO Ruby staining is currently the best method for global protein detection and identification in 2-DE gels, although this is yet to be shown by the wider proteomics community.

Recently, several multiplexed fluorescence approaches have been reported in which general protein staining with SYPRO Ruby is combined in the same gel with an additional fluorescence detection method, using a fluorophore with a different emission maximum. These other staining methods are used to probe for particular functionalities within the sample and have included the identification of glycoproteins by Schiff's base staining with the green fluorescent hydrazide dye Pro-Q Emerald 300, monitoring of in-gel β-glucuronidase activity using a fluorogenic substrate, and the identification of penicillin-binding proteins using BODIPY derivatives of penicillin.

A number of different fluorophores have been used to covalently derivatize proteins within gels or on membranes. These include fluorescein isothiocyanate, 5-(4,6-dichlorotriazin-2-yl) aminofluorescein, monobromobimane, 2-methoxy-2,4-diphenyl-3(2H)furanone (MDPF), and dansyl chloride. However, none of these are routinely applied for differential expression profiling. More recently, several approaches have been used to covalently label proteins prior to 2-DE separation or following IEF but prior to SDS-PAGE. These methods have used monobromobimane and 5-iodoacetamidofluorescein to label the cysteine sulfhydryl groups of reduced proteins, or MDPF and 5-(4,6-dichlorotriazin-2-yl) aminofluorescein to label ε-amino groups of lysine residues and N-terminal α-amino groups. Perhaps the most promising recent development in this kind of strategy is the use of two or three spectrally distinct fluorescent cyanine dyes (Cy2, Cy3, and Cy5), which allows differential labeling of multiple samples for separation and comparison on the same 2-DE gel. This technique, known as *2D-difference gel electrophoresis*, is discussed in detail in the next section.

2 Fluorescence 2D-difference Gel Electrophoresis (2D-DIGE)

2.1 Background

Conventional 2-DE gel-based differential protein expression analysis requires comparison of protein levels across multiple samples (see Sect. 1.1). However, inherent variations in the way proteins resolve in one 2-DE gel versus another makes image superimposition and rigorous quantitation of differential expression a difficult and inaccurate process. Such gel-to-gel variations arise for a number of reasons, including heterogeneity across polyacrylamide gels, differential thermal fluctuations, electric and pH field differences and variable precipitation of samples in the first dimension. This inherent variation in the technique means that there is an absolute requirement for separation of multiple replicate samples and image analysis/spot matching across many gels in order to measure statistically significant alterations in spot intensities. This process makes conventional 2-DE expression profiling very labor-intensive, particularly when many different samples are to be compared. Moreover, as described above, some of the commonly used methods of protein detection give variable staining from gel to gel, and lack the sensitivity and dynamic linear range of detection for expression profiling of complex biological samples.

To overcome these problems, Unlu and coworkers devised a methodology for detecting differences in two protein extracts run on the same 2-DE gel. This technique, known as *fluorescence 2D-difference gel electrophoresis*, utilized chemical derivatives of spectrally distinct fluorescent cyanine dyes (Cy3 and Cy5) for labeling two different samples prior to separation on the same 2-DE gel. The resolved, labeled proteins are then detected at the appropriate excitation and emission wavelengths for Cy3 and Cy5 using a multiwavelength fluorescence detection device (see Sect. 2.5). In this way, the two samples are subjected to the same procedures and microenvironments during separation, thus raising the confidence with which protein changes between samples can be detected and quantified, as well as reducing the number of gels that must be run.

2.2 Fluorescent Cyanine Dye Derivatives and Sample Labeling

The cyanine dye derivatives used in 2D-DIGE are *N*-hydroxy-succinimidyl (NHS) esters of propyl-Cy3 and methyl-Cy5 (Fig. 1). These dye derivatives will undergo nucleophilic substitution reactions with primary amino groups (i.e. ε-amino groups of lysine residues and N-terminal α-amino groups) in a protein sample, resulting in covalent modification with the cyanine moiety and loss of the NHS leaving group. These reagents were designed so as not to perturb the relative electrophoretic mobility of differentially labeled proteins during 2-DE. Thus, the dyes are both mass and charge matched, and carry a single positive charge that matches that of the lysine residue to be modified. The addition of the relatively hydrophobic cyanine moiety to proteins was reported to cause sample precipitation that was dependent upon the extent of labeling. Thus, optimal conditions were established for ''minimal'' lysine labeling, where an estimated 1 to 2% of all lysine residues in a whole-cell lysate were labeled without detectable effect on protein solubility. This effectively means

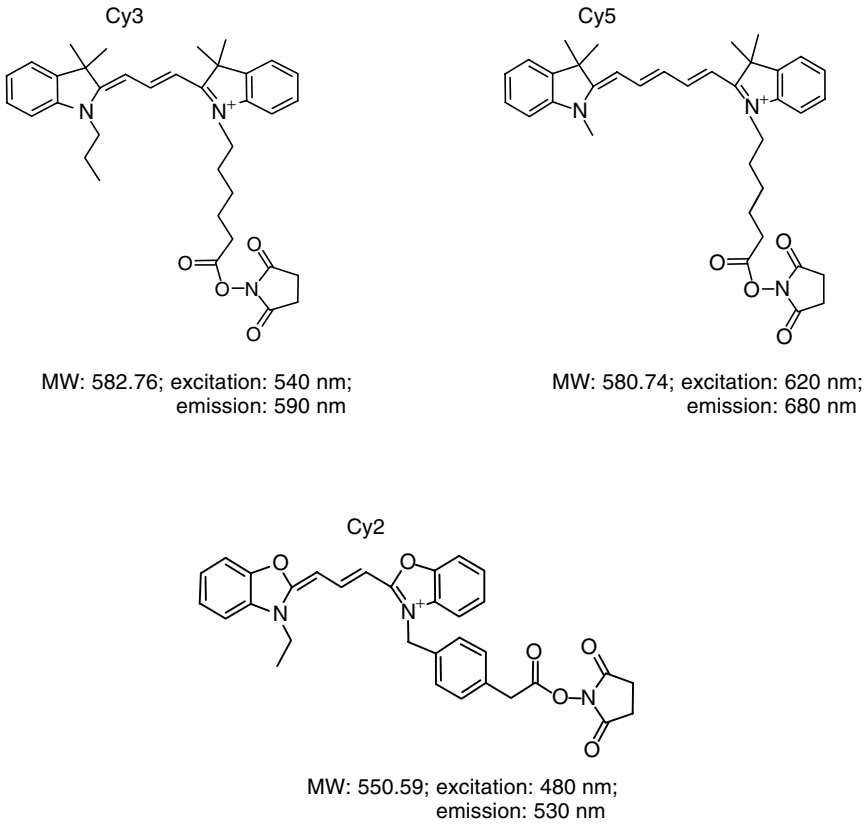

Fig. 1 *N*-hydroxy-succinimidyl esters of propyl Cy3, methyl Cy5, and Cy2 used for 2D-DIGE differential labeling of lysine residues. Molecular weights, excitation maxima, and emission maxima are shown.

that a minority of proteins is labeled on a single lysine residue, while the remainder is unlabeled. Reactions were carried out in an IEF-compatible lysis buffer (8 M urea, 2.5% CHAPS, 5 mM DTT and 5 mM HEPES) at pH 8.0 using 16 µmol dye per 1 µg total protein for 30 min on ice. Unreacted dye was inactivated by addition of an excess of 1,3-diamino-2-hydroxy-propane. Using this two-color 2D-DIGE methodology, the authors were able to successfully detect a single protein difference between two complex protein mixtures at the low nanogram level. This ''minimal'' labeling is also advantageous as it is unlikely to interfere with downstream in-gel tryptic digestion and MS identification of peptides.

The 2D-DIGE technology was acquired by Amersham Biosciences and is commercially available as the Ettan™ DIGE system. A third spectrally distinct cyanine dye, Cy2, has been introduced (Fig. 1), allowing simultaneous analysis of three samples on one gel. In an optimized protocol, labeling is performed using 4 to 8 pmol of dye per microgram of protein with an estimated dye: protein labeling ratio of <5%. Labeling is performed on ice in the dark for 30 min and any unreacted dye is inactivated by addition of a 50-fold molar excess

of free lysine for 10 min. The samples are then reduced with DTT and IEF sample buffer is added to the desired volume prior to 2-DE separation. Thus, labeling takes approximately 45 min, making it faster than any other staining method. In typical expression profiling experiments using the three-dye system, one of the dyes is reserved for labeling of an internal standard, usually comprising of a pool of equal amounts of all the test samples that are to be compared (Fig. 2). This internal normalization standard is then run on all gels against pairs of the test samples labeled with the other two dyes. Compared to the usual method of global normalization, normalization using the same standard on multiple gels allows direct comparison of the ratios of expression of a particular protein across the multiple samples. This greatly increases the ability to distinguish biological variation from gel-to-gel variation.

2.3 Validation and Sensitivity of 2D-DIGE

In a very rigorous validation of the method, Tonge et al. determined the quantitative variability in the 2D-DIGE process by applying it to mouse liver homogenates from control versus paracetamol-dosed animals. Using ImageMaster software, the authors established statistically valid thresholds for assigning quantitative changes between samples and found that these thresholds depended on the normalized spot volume, with lower volumes having significantly higher thresholds. This variation was correlated with the efficiency and sensitivity by which ImageMaster defines spot borders, which are less clear for low-intensity spots. Despite this, these thresholds were found to be unaffected by the Cy dye combination used or the individual operator, properties that demonstrate the robustness of the 2D-DIGE system. As for its application to expression profiling, Tonge et al. were able to identify significant changes in the expression of numerous proteins between control and paracetamol-treated mice, some of them novel, and also demonstrated that there was more variation between individual animals than was contributed by the error inherent to the 2D-DIGE protocol.

In another study using protein standards, it was reported that the linear dynamic range of detection for DIGE extended over five orders of magnitude, making it better than any other nonradioactive detection method. These authors also used ''spiking'' experiments to show that quantitation by DIGE was linear over at least three orders of protein abundance. The linearity and sensitivity of DIGE labeling was also tested by Amersham Biosciences on protein standards, and is shown to give a linear response from 1 to 10 000 ng (four orders of magnitude) and a detection limit of 0.25 to 0.95 ng, making it slightly more sensitive than silver or SYPRO Ruby staining. Despite this, we have reported that SYPRO Ruby detection on 2-DE gels reveals around 1.4 times the number of gel features than Cy dye labeling (Fig. 3 and. In this case, the Cy dye and SYPRO Ruby imaging was performed on the same imaging device using maximum exposure times without saturation of the most intense signals. However, by increasing exposure times it is possible to increase the overall sensitivity while saturating only a few of the signals from the more abundant protein spots.

A modified version of the original 2D-DIGE method has also been reported using the succinimidyl ester Alexa 488 and Alexa 532 fluorescent dye kits from Molecular Probes. Here, the degree of

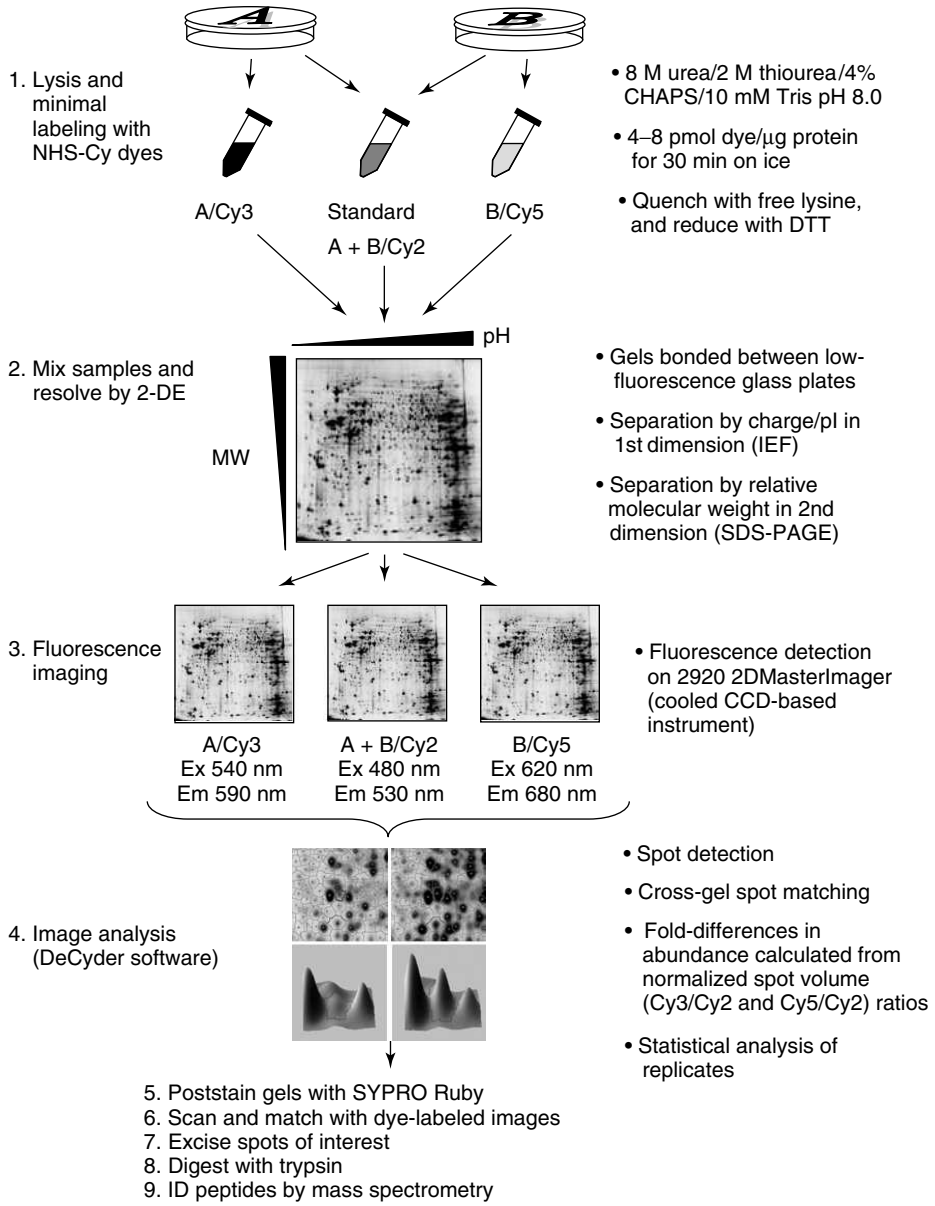

Fig. 2 Schematic representation of the 2D-DIGE protocol for minimal lysine labeling and using an internal standard for normalization.

labeling was calculated to be about 4-mol dye per mol protein and the sensitivity was reported to be similar to that obtained using a silver-staining kit (BioRad). A spiking experiment was used to show the linearity of the system and the ease with which differences could be identified using only simple image analysis software such

as Adobe Photoshop. Taken together, these studies demonstrate the robustness of the 2D-DIGE technique.

2.4 Cy dye-Induced Molecular Weight Shifts, Poststaining and Spot Picking

While minimal lysine labeling does not significantly alter the pI of proteins in 2-DE gels, it does cause a noticeable and somewhat variable shift in molecular weight because of the added mass of the dye (~460 Da). This mass shift, where the small percentage of labeled protein migrates more slowly than the corresponding majority of unlabeled protein, can be visualized by superimposition of the fluorescence 2-DE gel image with the corresponding poststained image (e.g. SYPRO Ruby stained). The shift is particularly noticeable in the lower molecular weight region of the gel. (Fig. 3). Although this molecular weight shift does not pose a problem for analytical 2D-DIGE comparisons of spot intensities (since samples are labeled to the same extent), accurate excision of a protein from preparatory gels may be compromised, particularly in the low molecular weight range. This problem can be overcome by cutting a larger region of interest from the gel, or better still, by poststaining gels to visualize the more abundant unlabeled protein spots. Thus, the sensitivity of 2D-DIGE is limited by the need to limit the modification to single lysine residues to reduce the changes in apparent molecular weight between modified

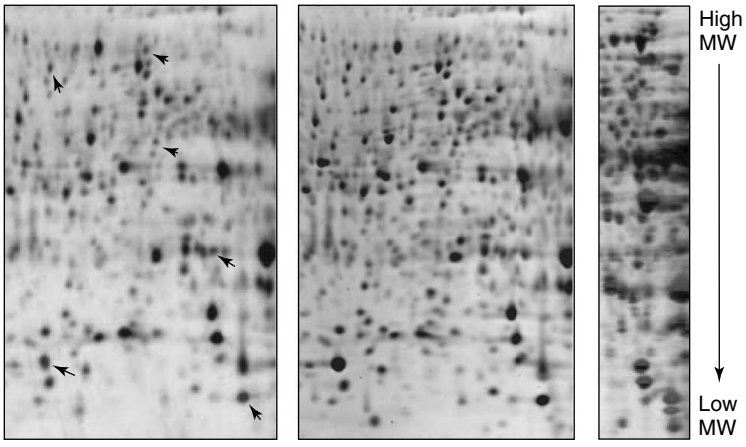

Fig. 3 (a) Merged 2-DE images of Cy3-labeled normal mammary luminal epithelial cell lysate (red) and Cy5-labeled ErbB-2 overexpressing luminal epithelial cell lysate (blue). Arrows indicate some of the obvious differences in expression between the two cell lines, (b) SYPRO Ruby poststaining of the same gel showing detection of a greater number of gel features. (c) Superimposition of a Cy dye gel image (blue) and SYPRO Ruby poststained gel image (red) revealing the shift in molecular weight due to dye labeling (figure adapted from Gharbi, S., Gaffney, P., Yang, A., Zvelebil, M.J., Cramer, R., Waterfield, M.D., Timms, J.F. (2002) Evaluation of two-dimensional differential gel electrophoresis for proteomic expression analysis of a model breast cancer cell system, *Mol. Cell. Proteomics* **1**, 91–98). (See color plate p. xxi.)

and unmodified proteins, so as not to compromise downstream identification of proteins by MS.

We, and others, have found that poststaining of dye-labeled proteins in 2D-DIGE gels with CBB, silver, or SYPRO Ruby is not compromised, and facilitates the spot-picking process. However, problems have been reported with silver or CBB poststaining of proteins labeled with Alexa dyes. This is likely to have been caused by masking of proteins by the bound dyes, which were used at a higher stoichiometry of labeling than the Cy dyes. SYPRO Ruby seems to be the best-suited method for poststaining since it is both sensitive and compatible with downstream MS identification of excised protein spots (see Sect. 1.3). It is also worth noting that bonding of gels to glass plates using bind-silane (see Sect. 2.5), severely reduces the sensitivity of MS-compatible silver staining, whereas the end-point SYPRO Ruby staining is unaffected. Moreover, SYPRO Ruby detection can be performed on the same fluorescence detection device as the Cy dye detection.

2.5 Fluorescence Detection and Image Analysis

Instrumentation for fluorescence detection of covalently derivatized or non-covalently stained proteins is currently based on either laser/photomultiplier tube (PMT) scanning or lamp/charge-coupled device (CCD)-based mechanisms. Laser/PMT-based instruments include the Molecular Dynamics™ Typhoon™ 9400 Variable Mode Imager and the Fuji Photo Film Company FLA-2000 Fluorescent Image Analyzer, while xenon arc lamp/CCD-based instruments include the Perkin Elmer Life Sciences Wallac-1442 ARTHUR™ Multiwavelength Fluoroimager and a variant of this, the Amersham Biosciences 2920 2DMasterImager™. A schematic of the CCD-based 2920 2DMasterImager™ is represented in Fig. 4. The CCD-based instruments tend to be more versatile since wavelength selection for different fluorophores can be customized using appropriate emission and excitation filters and do not rely on the output of a laser source. Although both types of imaging system can deliver resolutions as high as 50 µm, which is more than adequate for detection of 2-DE gel spots, some high-resolution CCD devices must work by collecting multiple images over the sample that are then stitched back together to form a composite of the whole image. This strategy increases the scanning time significantly, but can also create a patchwork effect of different background intensities across the image, particularly when the signal intensity is low.

In terms of efficiency of workflow, gels are best cast and run between low-fluorescence glass plates and then imaged between the plates directly after the second dimension run (Figs. 2 and 4). This prevents drying of gels during long imaging times and sets a fixed position for all images from a particular set of gels. As mentioned above, gels are best poststained prior to picking, because of the molecular weight shift caused by dye attachment. However, direct spot-picking without fixing and poststaining may increase the yield of recovered peptides from gel pieces for MS, as long as the spots can be accurately excised. We have also found that it is optimal to bond gels to one of the glass plates with bind-silane at the casting stage. This approach maintains the gels in virtually the same fixed position after poststaining, facilitating alignment of Cy dye and poststained images and allowing for safer

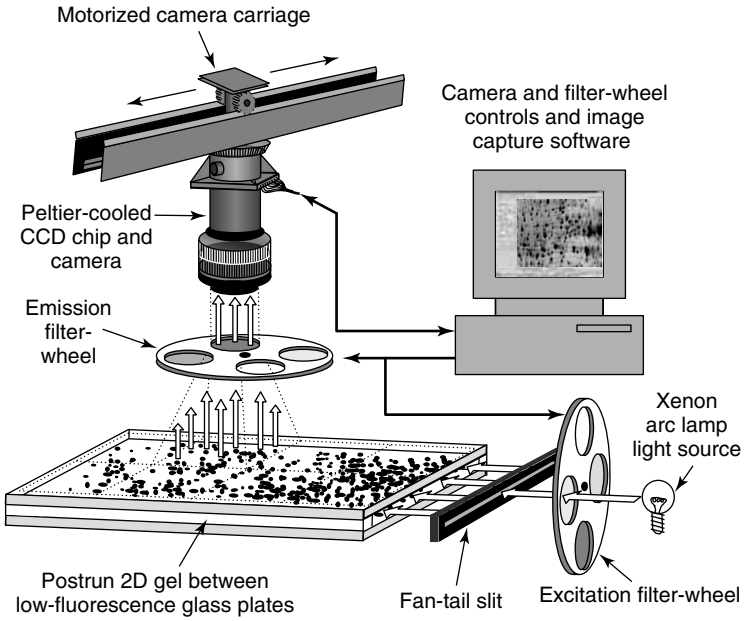

Fig. 4 Schematic representation of a xenon lamp/CCD-based fluorescence imager (based on the Amersham Biosciences 2920 2DMasterImager™). The gel is imaged *in situ* between low-fluorescence glass plates directly after the 2-DE run. Images are collected separately for the three Cy dyes using filter wheels for the appropriate excitation and emission wavelengths. SYPRO Ruby poststained gels are scanned on the same instrument, again using the appropriate light filters.

gel storage. Bonding is also an absolute necessity for most automated spot-picking platforms; however, it is important to note that milder fixing conditions must be employed when staining bonded gels in order to prevent overshrinkage and tearing of gels.

Numerous commercially available software packages have been used for spot detection and to match and evaluate spot intensity or volume differences across multiple gels. While all require some level of user intervention resulting in loss of reproducibility, their accuracy is still dependent on the inherent variability of 2-DE separations and protein staining. It is also important to be aware that there is variability in spot detection using different image analysis packages, so it is important for an investigator to determine prediction thresholds for their particular system (see Sect. 2.3). Although not available at the time of the original validation, 2D-DIGE-image analysis is most easily performed using DeCyder Differential Analysis Software (Amersham Biosciences). This software is split into two modules. The differential in-gel analysis (DIA) module is first used to detect overlapping, differentially labeled spots within the same gel, performing automatic background subtraction, quantitation, and normalization with the internal standard. The biological variation analysis (BVA) module then matches detected spots across gels and performs a statistical analysis (Student *t*-test

and 1-way and 2-way ANOVA analyses) to find consistent differences across replicate samples. This software package thus avoids the need for the investigator to set prediction limits, and is a far cry from a previous study in which a looped two-frame movie of Cy3 and Cy5 images was used to investigate proteomic changes in cardiac mitochondria associated with loss of creatine kinase. Although this was not a good way to quantify changes in protein abundance due to the lack of normalization, this method does demonstrate the simplicity of the DIGE process. A further advantage of the DeCyder software is that all matched spots are given the same spot identifier from gel to gel. This greatly assists in data analysis for multiple samples and in subsequent sample tracking, handling, and MS identification.

2.6 Applications

DeCyder software was used in a three-dye 2D-DIGE differential expression analysis studying the oncogenic effects of ErbB-2 overexpression and growth factor treatment in human mammary luminal epithelial cells. Protein expression over time (4 time points of growth factor treatment) and between two cell lines (normal versus ErbB-2 overexpressing) was simultaneously examined in triplicate in a single experiment. Thus, eight triplicate cell lysates (24 samples) were labeled with Cy3 or Cy5 and run against a Cy2 standard comprising a pool of all 24 samples (36 samples in total). After appropriate mixing, 12 gels were run with 300 μg of total protein, generating 36 images for DeCyder analysis. Although spot matching was not perfect across all gels for all features (i.e. less than 36 out of 36 matches for all spots), the analysis identified changes in the abundance (by spot volume) of numerous features with time and/or between cell lines that were significant within a 95% confidence limit ($p < 0.05$). Moreover, statistically valid differences could be detected for features that were only 1.3-fold up- or downregulated in ErbB-2 overexpressing cells versus normal. Spots of interest were excised from the same dye-labeled gels following SYPRO Ruby poststaining, imaging, and alignment, using a Syprot automated spot picker (Amersham Biosciences). Around 30 of the differentially regulated protein features were identified by MALDI-MS. While several of these proteins may contribute to ErbB-2-dependent transformation, the others are likely to be deregulated as a secondary consequence of the enhanced proliferation and morphological changes resulting from ErbB-2 overexpression.

2D-DIGE and DeCyder analysis were also applied to study the effects of benzoic acid treatment on the *Escherichia coli* proteome. Although only Cy3 and Cy5 were used, Cy3 was used for labeling of a pooled internal standard, and run against Cy5 labeled untreated or benzoic acid–treated cells. Using this internal standard method, a more accurate quantitative analysis was achieved compared to conventional 2-DE, and 179 differentially expressed protein spots were subsequently identified from gels by MALDI-MS. This study not only revealed the complexity of the response to benzoic acid treatment but also showed that membrane proteins and different protein isoforms could be analyzed using this method. In a slightly different application of the method, reciprocal labeling with Cy3 and Cy5 was used to identify reproducible and common compensatory changes in the whole brain tissue proteomes of five different genetically altered mouse models. With MALDI-MS identification, this analysis

revealed an isoform change in the heat shock 70 related protein, mortalin, and an alteration of the antioxidant protein 2, indicating that stress-responsive pathways may be altered artifactually in genetically modified mice. Finally, Zhou et al. have demonstrated the use of 2D-DIGE in quantifying differences in protein expression between laser capture microdissection–procured esophageal carcinoma cells and normal epithelial cells from the same human tumor-tissue sample. Analysis of Cy3- and Cy5-labeled lysates from approximately 2 50 000 cancer cells and normal cells (200 μg each) revealed 1038 and 1088 protein spots respectively. DeCyder DIA analysis showed that 58 spots were upregulated by > threefold and 107 were downregulated by > threefold in cancer versus normal cells, although only three proteins were subsequently identified by LC-MS/MS from SYPRO Ruby poststained gels. Normalization was performed using the total pixel volume of each image, rather than the internal standard method described above. Since replicate samples were not compared, the reproducibility and significance of the data is unclear, although this study does demonstrate the power of the 2D-DIGE technique for differential expression analysis of limited sample amounts.

In summary, these reports demonstrate that 2D-DIGE can be applied to provide sensitive and reproducible analysis of differential protein expression between two or more biological samples, be they cell lines, sorted cell types from tissues, whole tissues, or whole microorganisms. Since 2D-DIGE offers increased experimental confidence and accuracy in detecting quantitative protein changes while at the same time reducing experimental workload, it is a particularly advantageous technique for high throughput–expression proteomics. Moreover, the apparent compatibility of the technique with subsequent identification of protein spots from gels by MS further reinforces this notion.

3 Perspectives

The limitations of 2-DE-based approaches for differential expression analysis is worth mentioning. A standard broad pH-range 2-DE gel loaded with 200 μg of cell lysate may resolve between 2000 and 2500 protein features using the most sensitive detection methods. However, these features represent the most abundant and long-lived housekeeping proteins that can mask lower-abundance proteins, thus reducing the resolving power of 2-DE gels. Detection and identification of 1 ng (current detection limit of the best staining methods) of a 50-kDa protein at 100 copies per cell, would require separation of total protein from around 1.25×10^8 cells. Assuming 100% recovery of the protein of interest, this may represent up to 20 mg of total protein, a load that is too great for high-resolution 2-DE separation. A further problem is that hydrophobic, highly insoluble, very basic, or very small/large proteins are not well represented in 2-DE gel-based separations.

One approach to improving the detection of lower-abundance proteins has been to run larger amounts of material on narrow pH-range IEF ''zoom'' gels. Although this becomes very labor-intensive when a global expression analysis is required, DIGE labeling could easily be applied to this strategy, improving both efficiency and accuracy. Another approach has been the prefractionation of samples, for example, using affinity chromatography or subcellular fractionation prior to 2-DE

separation. Such methods work by reducing the dynamic range of protein expression within a sample as well as by reducing its complexity. However, prefractionation procedures should be kept as simple as possible to avoid sample-to-sample variation, they should target different molecular properties of proteins compared to 2-DE separation, and should be conducted under conditions that minimize sample loss, degradation, or introduction of artifactual protein modifications. Subcellular fractionation has already been combined with 2D-DIGE analysis to identify targets of paracetamol toxicity in liver mitochondrial subfractions and changes in murine cardiac mitochondrial proteins associated with loss of creatine kinase. In the first study, very rapid changes were seen in the levels of many proteins, indicating posttranslational modification rather than changes in gene regulation per se. This not only demonstrates the power of 2-DE over non-gel-based methods for resolving specific isoforms of proteins, but also shows the potential of 2D-DIGE for the accurate analysis of changes in posttranslational modifications.

In the move away from 2-DE-based methods, several gel-free proteomic strategies have been recently developed. Rather than relying on protein separation, these methods are based either on multidimensional chromatographic peptide separation linked to high-throughput MS, or more recently, direct protein recognition and selection on arrayed protein chips. Although protein microarray technologies could ultimately provide high-throughput screening of biological activities and even protein expression levels, they are as yet limited in terms of their availability and the number of targets. Another recently developed method known as *isotope-coded affinity tagging* (ICAT) combines multidimensional chromatography and differential isotope labeling for comparative quantitation of two samples by LC-MS/MS. Although the ICAT method circumvents the problems associated with 2-DE separations, the two methods have been combined, and like DIGE, this allowed the relative quantitation of proteins in two samples separated on the same 2-DE gel. Despite the emergence of these gel-free proteomic strategies, they have yet to prove themselves for the quantitative analysis of multiple samples.

Although in its infancy, 2D-DIGE will undoubtedly become more widespread as a protein expression profiling technique. It is as sensitive as existing 2-DE methodologies, but provides greater statistical accuracy for comparison across multiple samples while at the same time decreasing the workload. One can envisage the development of additional fluorescent protein tags that would allow more than three samples to be analyzed on the same 2-DE gel. Moreover, these tags could be used to target residues other than lysine, or to allow functional labeling of subsets of the proteome. For example, our lab and others are currently developing strategies for the labeling of reduced cysteine thiol groups with iodoacetamide or maleimide versions of the Cy dyes. Since cysteine residues occur at a much lower frequency than lysine residues, this strategy offers the potential for higher stoichiometry labeling and hence higher sensitivity, without adversely affecting the solubility and/or migration of proteins. The addition of affinity tags to these reagents would also allow enrichment of only the labeled subset of proteins, thereby reducing the complexity of biological samples and increasing the yield of low-abundance cysteine-containing proteins.

In terms of functional probes, cysteine labeling with iodoacetylated Cy dyes could

be applied to monitor changes in the oxidation state of certain proteins. The rationale behind this is that thiol groups are often targets of cellular oxidation, and an oxidized thiol group in a target protein would no longer be able to react with the iodoacetylated Cy dye. Indeed, we have preliminary evidence that high stoichiometry labeling of unreduced samples using these Cy dye derivatives can be used to monitor changes in cysteine reactivity in cells during oxidative stress induced by hydrogen peroxide treatment. Recently, BODIPY derivatives of a specific inhibitor have been used as chemically reactive fluorescent probes to covalently label the active site thiol group of cysteine protease family members. This novel functional proteomic approach allowed profiling and identification of active cysteine proteases in complex protein mixtures, and was used to monitor protease activity for the screening of small-molecule inhibitors directed against each enzyme family member. It is likely that other fluorescent probes for functionality will soon be designed and used for proteomic profiling of complex biological samples. With this in mind, the future of differential fluorescence labeling in proteomics looks bright.

Keywords

Chromosomal Bands
Transverse light and dark bands on the chromosomes produced by different staining techniques.

CpG Islands
Dinucleotide motif of a cytidine and guanidine (5′-C-p-G-3′), commonly unmethylated, within a GC-rich chromosomal domain.

EST (Expressed-Sequence Tag)
Short (300–500 nucleotide) single read DNA sequence derived from a randomly selected cDNA clone.

Exon
A coding DNA segment within a gene.

GC Content
The distribution of Guanine and Cytosine nucleotides among the genome, which is correlated with various structural and functional properties of the genome fragments.

Intron
A noncoding DNA segment within a gene.

Isochores
Long DNA segments, usually greater than 300 kb, which are characterized by a fair compositional homogeneity.

Promoter
DNA segment composed of the first few hundred nucleotides located ''upstream'' (on the 5′ side) of a gene, and which controls the transcription of such a gene.

Transcript
mRNA sequence produced by transcription from DNA.

Splicing
The process that removes all the introns to produce mature mRNA.

The human genome encodes the information about the development, physiology, and evolution of our own species. Among the whole DNA stretch with more than 3000 million nucleotides, the most interesting portions are those composed of genes, the DNA fragments that code for a defined biochemical function, such as the production of a particular protein. It is believed that genes are responsible for the major biological functions of the genome, and knowledge about them and their encoded proteins is crucial for basic biology, biomedical research, biotechnology, and health care.

In this contribution, we provide an overview of the ongoing research on the gene distribution in the human genome. It has been known for a long time that the distribution of protein-coding genes among human chromosomes is extremely uneven. DNA fragments with different gene densities show different compositional properties, which are believed to be correlated with gene composition, function, and evolution. Around 98% of the human genome does not code directly for proteins and therefore was once dismissed as ''junk DNA.'' However, many studies have shown that these ''junk'' sections contain many important features essential for the biological function of a genome. The challenge to understanding how genomes ''work'' involves more than just the identification of protein-coding segments. We must understand the mechanisms by which all the components of a genome interact to produce a functional cellular system.

1 Macroscale Distribution

In order to perfectly define the human genome, it would be necessary to precisely locate each and every single gene. At present, this is not possible because gene identification from the human genome drafts is a complicated process given the multiple sequence elements that combine to ultimately produce (express) an operational gene. A gene is a locus of cotranscribed exons, which in the human genome tend to be short. Exons are separated by introns, which are sequences of long lengths (some of them exceeding 10 kb) that do not code for protein sequences. Transcription of a gene domain produces heteronuclear RNA (hnRNA), which is a linear copy of the coding DNA strand (except with complementary nucleotides). This hnRNA transcript contains all the exon and intron sequences. Posttranscriptional RNA processing splices out the intronic sequences and prepares the RNA transcript for translation as a mature messenger RNA molecule (mRNA). What is surprising is that these mature coding segments of mRNA (which are responsible for producing all the proteins in our bodies) represent only ~1.5% of our total genome DNA sequence. Thus, looking for

genes in our genome is like looking for needles in a haystack. In addition, a single gene may give rise to multiple transcripts by alternative splicing, and alternative transcription initiation and termination sites. Given the current limited knowledge about gene structure and function, none of the existing algorithms for gene prediction and annotation are perfect, and therefore we can only estimate the gene distribution based on our current understanding of how genes are structured and expressed.

1.1 Gene Number Estimates

Before the publication of the human genome drafts, estimates of the total number of genes in humans were proposed in the literature. However, different approaches produced different estimates, with some as high as 120 000, even when the methods utilized for the estimation were similar. One of the reasons for this variability was the necessity to use strong assumptions in order to obtain the estimate, which made it very difficult to assess the reliability of the predicted number. For instance, Ewing and Green estimated the number of genes by comparing a database of ESTs (expressed-sequence tags) with chromosome 22 and with a nonredundant set of mRNA sequences. The idea, explained in more detail in their work, is to estimate the total number of genes by counting the amount of overlap between two sets of genes obtained independently. Both comparisons (ESTs with chromosome 22 and ESTs with the mRNA sequences) produced an estimate in the order of 35 000 genes. This estimate is very different from the 60 000–70 000 genes predicted by Fields et al., who used a similar method to compare a set of ESTs with mRNA sequences. The difference is that Ewing and Green eliminate single unconfirmed ESTs in the counting process, thereby resulting in a more conservative estimate. Other methods predicted 80 000 genes by estimating the number of CpG islands in the genome and assuming that all islands are associated with genes and that 56% of the genes have an island. These assumptions were challenged by Ewing and Green, who suggest an estimate below 30 000. Other gene number estimates based on reassociation kinetics and genome comparisons with other species also produce very different results.

With the publication of the two drafts of the human genome sequence (The human genome sequence is available at http://genome.ucsc.edu/) in 2001, more comprehensive studies about gene distributions in the human genome have become possible. Although the genome sequence is still being updated, both the public and the private sequencing efforts have obtained similar estimates of around 30 000 genes for humans. These studies, however, are far from being complete and conclusive. There are several difficulties: first, the draft sequences do not provide a perfect coverage of the human genome and there are still errors in the sequence data. Therefore, even the best estimate from the sequence might not be close to the real one. Second, and more importantly, gene extraction from the genome is not a trivial task, and even the best gene prediction tools are not likely to be 100% reliable. Therefore, it is fair to say that our knowledge about the gene distribution in the human genome, although much better than before the publication of the draft sequences, is still far from complete. For instance, the work of Das et al., published after the human genome draft, suggests, by using experimental evidence, a higher estimate in the range between

41 000 and 45 000 genes is obtained. As we will see in the following sections, these estimates are still based on some assumptions. However, as an advantage over other methods that do not use direct sequence data, the availability of the genome draft allows the refinement of these assumptions. Notice also that the methods that are applied directly over the genome sequence to identify genes obtain not only estimates about the gene number but also about the gene distribution.

1.2 Gene Prediction

There are different methods to locate genes in the human genome. The simplest one is to perform alignments between known genes contained in databases such as RefSeq and the genome sequence. Although this approach is very powerful to locate genes that are already known, it does not allow the discovery of any new genes. Another related possibility is to make gene predictions by performing sequence comparison with previous known genes and proteins in other organisms. As before, the problem with this approach is that it cannot extract new genes, since, obviously, they are not included in the comparison set. A third method is based on homology studies between the genome sequence and libraries of ESTs. Obviously, the success of this method depends on the completeness and quality of the libraries, which should consist of relatively large ESTs matching the genes. Finally, *de novo* (*ab initio*) techniques try to recognize groups of exons directly from the genome sequence. In order to do so, these methods define gene models using *a priori* information about the gene structure (sequence composition, intron/exon structure and length, splice sites, etc.), and perform gene extraction by identifying regions in the genome sequence that correspond to the gene model.

Several models have been used in different *ab initio* methods, including neural networks, decision trees, and, more frequently, hidden Markov models (HMMs), which are the base of well-known tools such as Genscan and Genie. If our understanding of the cell mechanisms to identify genes were complete (or in other words, if *a priori* information about the gene structure were perfectly available), and provided that the DNA sequence were perfectly known, *ab initio* techniques would be able to extract and locate all genes contained in the genome. Unfortunately, this *a priori* knowledge is not available, and the lack of knowledge leads to several types of errors in gene prediction:

- False positives, resulting when sections of the genome sequence that do not correspond to genes are identified as such by the prediction method. This type of prediction error can occur for several reasons such as spurious predictions due to alignments produced by chance or by the presence of pseudogenes.
- Missing genes, resulting when sections of the genome corresponding to genes are not identified as such by the prediction method. This type of prediction error can occur for several reasons, including the inability of the method to either detect all gene components or to properly connect correctly detected components (fragmentation).
- Inaccurate genes, resulting when a gene is identified but the prediction is either incomplete or partially wrong. This type of prediction error occurs when the method misses some exons or incorporates wrongly predicted exons in the gene prediction.

The gene prediction methods just mentioned are not mutually exclusive. In fact, they are usually applied together with the objective to develop complex prediction tools capable of achieving the best possible sensitivity and specificity – that is, joint optimization to miss as few genes as possible with the least number of false positives.

1.2.1 Public Consortium

The first step in the effort from the public consortium to predict genes in the human genome draft is to utilize the Ensembl system. This system uses the *ab initio* tool Genscan to generate gene predictions that are confirmed by similarities to ESTs, mRNAs, and protein motifs. Each gene component (exon/intron) is confirmed independently, which increases the likelihood of fragmentation. In order to reduce this fragmentation, Genie, another *ab initio* technique, is utilized jointly with Ensembl. These Ensembl/Genie results are compared with known genes contained in RefSeq, SWISSPROT, and TrEMBL databases. At the end of this process, the total number of gene predictions is almost 32 000. From this prediction, approximately 15 000 of them correspond to known genes, 4000 come from the combination of Ensemble and Genie, and 13 000 from Ensembl alone.

In order to validate the quality of these predictions, different approaches are utilized to estimate the sensitivity and specificity of the prediction stage. The first approach used in the landmark paper of the public consortium is to compare these predictions with new independently discovered genes not used in the prediction process. Thirty-one genes newly discovered in chromosome X were considered in the aforementioned paper. From these genes, 28 are included in the draft, and 19 were successfully predicted, which gives an estimate for the sensitivity of the gene prediction process of 68%. Moreover, on average 79% of each gene was detected and the fragmentation can be estimated as 1.4 gene predictions per true gene. However, this approach should be taken with caution because the number of genes limits the accuracy of the statistical analysis. A higher sensitivity of 85% is obtained in the second approach, when the predicted genes are compared to a set of 15 294 mouse cDNAs generated by the RIKEN Genomic Sciences Center. Specifically, 81% of the genes in the mouse showed similarity to the human genome sequence and 69% were similar to the predicted human genes, resulting in a sensitivity of $69/81 = 85\%$. The final approach compares the predicted genes with the gene annotations in chromosome 22, which consisted of 539 confirmed genes and 133 pseudogenes. This comparison suggests a rate of false-positive or spurious predictions (including pseudogenes predictions) at around 20%.

The final estimate of the number of genes results from the development showed above: 17 000 gene predictions of unknown genes with a 20% false-positive rate and a fragmentation factor of 1.4 lead to an estimate of 9500 new unknown genes. If these gene predictions are assumed to contain 60% of all previously unknown human genes (following the validation results in the previous paragraph), the number of previously unknown human genes can be estimated as 16 000. Considering also the 15 000 known genes contained in the human genome draft, the total number of genes in the human genome can be estimated to be around 31 000. Notice that this number is highly dependent on the estimates of

specificity, sensitivity, and fragmentation of the gene prediction method utilized for the analysis.

1.2.2 Celera Effort

In order to perform gene prediction, Celera Corporation, led by Craig Venter, developed an approach called *Otto*. Otto considers different lines of evidence to locate genes. The first step in the process is to identity gene boundaries by examining matches of the genome sequence to EST and protein databases. These matches are combined into bins in such a way that a single gene is expected for each one of the bins.

Then, different procedures are applied to extract genes. A first set of genes is extracted from the genome by comparing the transcript database RefSeq with these bins. A total of ~6500 genes resulted from this process, which identified genes when some transcript in the RefSeq database matched the genome sequence for at least 50% of its length with more than 92% identity. These ~6500 genes are the ones in which Otto has a higher confidence. For the rest of the genome regions that have sequence similarity but do not present a clear match to known genes, Otto considers four lines of evidence (similarity to known proteins, similarity to human ESTs and cDNAs, similarity to rodent ESTs and cDNA, and conservation between mouse and human DNA) and tries to develop a gene model using Genscan. If the model is reasonable, and predicted exons are supported by at least one of the lines of evidence, a gene is considered identified. The number of additional genes obtained in this way by Otto was ~11 000. Considering the ~6500 genes identified before, the number of genes predicted by Otto is ~17 500 if only one line of evidence is required. The number decreases to ~17 000, ~15 500, and ~12 500 if two, three, or four lines of evidence are utilized.

It is interesting to note that Otto does not try to directly identify genes with gene prediction tools such as Genscan. Instead, the gene boundaries are predicted by first looking at homology evidence. The reason for this approach is that most gene prediction methods have problems performing boundary prediction. The specificity, sensitivity, and fragmentation rate of this method are superior to those of Genscan. However, predictions from Otto are very conservative, since they depend on ESTs and some gene transcripts are not included in the existing databases. Therefore, Otto's predictions are complemented with additional ones produced by three *de novo* techniques (GRAIL, Genscan, and FgenesH). The number of *de novo* predictions that did not overlap with known genes or Otto results was around 58 000. From this number ~21 500 are supported by one line of evidence, ~8600 by two, ~5000 by three, and ~1900 by four. Therefore, the total number of predicted genes obtained by combining these predictions with the ones proceeding from Otto, would be ~39 000, ~26 500, ~23 000, and ~20 000 depending if one, two, three, or four lines of evidence are required for the *de novo* methods (and assuming that one line of evidence is enough for the Otto predictions). Around 1000 additional genes can be predicted by identifying regions outside the original bins where there was a match between an EST and the genome sequence across a splice junction, and at least one line of evidence was present.

1.3 Gene Distribution

As the sequencing of larger and larger regions of the human genome was

completed, there was a series of increasingly comprehensive gene maps constructed and cross-referenced to the human genetic map. The gene map published in 1996 by Schuler et al. confirmed an uneven gene distribution among different chromosome bands. Two years later, a new gene map with higher coverage and accuracy was published, showing that the distribution of genes across individual chromosomes presents striking fluctuations. Significantly, higher than average gene densities are found in chromosomes 1, 11, 17, 19, and 22, while lower than average densities are found in chromosomes 4, 5, 8, 13, 18, and X.

The publication of the two draft sequences in 2001 represents a milestone in the study on human genomics. We are now closer than ever to understanding how our own genomes are structured in terms of the distribution and organization of genes within and between chromosomes. The first, full, genome structural analysis was completed by the International Human Genome Sequencing Consortium (IHGSC), which aimed at creating an initial integrated gene index (IGI) and an associated integrated protein index (IPI) for the human genome. Then the chromosomal distribution of the IGI gene set was examined. On average, the gene density in the human genome is 11.1 genes per Mb. However, this number presents significant variations among chromosomes, from 26.8 genes per Mb for chromosome 19 to 6.4 genes per Mb for chromosome Y. The number for chromosome Y could be even smaller, because the high number of pseudogenes contained in chromosome Y is likely to have generated numerous false-positives from the gene prediction studies.

Several months after the publication of the human genome, a draft physical map with annotations for a majority of the human transcripts was published by Zhuo et al. The map was generated by assembling the sequence clusters in the UNIGENE database into nonredundant sequence contigs, and then aligning these clusters to the human genome draft. As shown in Fig. 1, the estimated transcript densities show a significant difference among all the human chromosomes. The

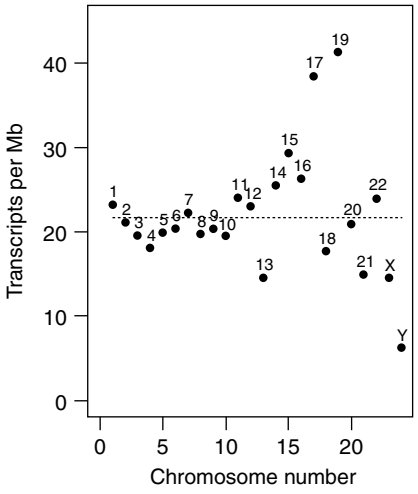

Fig. 1 Transcript densities on the different human chromosomes. The broken line indicates the average transcript density for the whole genome (from Zhuo, D. et al. (2001) Assembly, annotation, and integration of UNIGENE clusters into the human genome draft, *Genome Res.* **11**, 904–918).

highest density, found in chromosome 19, is above 40 transcripts per Mb, which is almost twice the value of the average density over the whole genome. The lowest gene densities were found in chromosomes X, Y, 21, and 13, which is consistent with the previous gene density estimates.

According to the record updated on January 25, 2003, there are 18 761 human genes reported in RefSeq that have their function and coding sequences known. Figure 2 shows the chromosomal distribution of these genes, excluding 225 genes that have not been located in the draft genome. The uneven gene distribution indicates that the human genome is organized in discrete regions, and that functional characteristics may get distributed in a related pattern.

2 Meso-scale Organization

With an estimate of around 30 000 genes and over 3 Gb nucleotides in the human genome sequence, the inevitable question that springs to mind is "where exactly are the genes located?" In other words, how are our 30 000 genes distributed over our 3 000 000 000 bp genome? Many contributions in the literature have tried to address this question during the last 30 years. As described in Sect. 1.3, genes are distributed unevenly among chromosomes. Moreover, different lines of evidence, which will be reviewed in this section, have led to the same conclusion: the gene distribution along each chromosome is conspicuously nonuniform. In this section, we move our observation from the

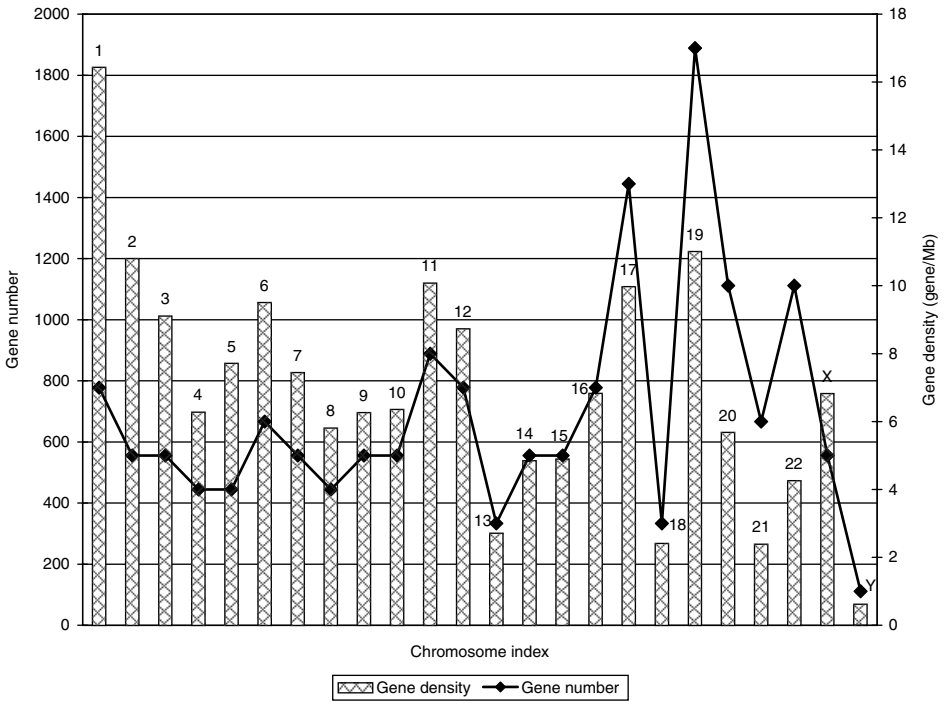

Fig. 2 Chromosomal distribution of the 18 761 genes reported in RefSeq as of January 25, 2003.

chromosome to a finer scale, and describe the gene distribution according to several biochemical features in the human genome.

2.1 Gene Distribution versus Chromosomal Banding

The uneven gene distribution in the human genome was hinted at long before the gene map on the whole genome was estimated, by the observation of the banding patterns produced when chromosomes are stained. More than 30 years ago, it was discovered that certain dyes selectively stain some regions of metaphase chromosomes more intensely than other regions, and that the resulting transverse banding patterns are specific for individual chromosomes.

Banding characteristics were readily applied for the identification of individual chromosomes. Shortly afterwards, other applications were discovered, with several studies showing that chromosomal bands might have functional and structural significance. Giemsa, for example, is a permanent DNA dye that has affinity for A + T rich DNA regions. After a pretreatment that denatures the DNA sequence with barium hydroxide, Giemsa darkens the regions of constitutive heterochromatin, DNA fragments that are always retained in a compact organization and contain almost no active genes. These dark bands are called C-bands and cover around 17 to 20% of the human chromosome complement. They are mostly distributed in pericentromeric regions. One exception is the Y chromosome that has a relatively large heterochromatic segment in its long arm, suggesting a low gene density on that chromosome.

The remaining 80% of the genome, the euchromatic component, is divided into G-, R-, and T-bands. G-bands are produced by staining the chromosomes with Giemsa, after subjecting them to a brief proteolytic treatment. R-banding (referred to as reverse Giemsa, since the resulting bands are roughly the reverse of G-bands) requires pretreatment of the chromosomes, prior to Giemsa staining, in a hot physiological alkaline solution. Under such conditions, the AT-richer DNA sections are denatured faster, reducing their affinity for Giemsa staining. Finally, T-bands are an extremely heat-resistant subset of R-bands, obtained by repeating the heat pretreatment. The distribution of all these bands along the human chromosomes is shown in the ideograms (Fig. 3), which are used broadly in cytogenetic analyses (e.g. for the detection of chromosome aberrations causing disease).

Chromosomal bands correspond to chromosome domains with different properties. For instance, it has been shown that early and late phases of mammalian DNA replication correlate with the banding pattern: R-bands replicate early, while G-bands are associated with a late replication time. This result has been confirmed by analysis of replication times across R/G boundaries. Moreover, the work of Matassi et al. has revealed that genes located closely on a chromosome have similar evolutionary rates, which may imply a relationship between evolutionary rates and chromosomal bands. One of the most interesting properties is the relationship between gene density and chromosome bands.

Chromosomal bands exhibit a clear correlation with gene density: Generally speaking, the gene density of R-bands is higher than that of G-bands.

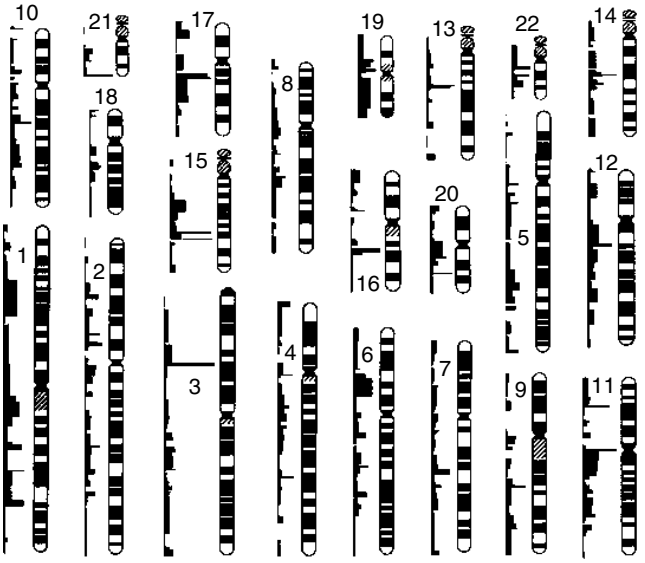

Fig. 3 Gene distributions on chromosomes 1–22. A plot of the average number of estimated gene *loci* across a moving window of 100 Kb is aligned to the ideograms of each chromosome. Genes are heterogeneously distributed both within and among chromosomes (see Caron, H., et al. (2001) The human transcriptome map: Clustering of highly expressed genes in chromosomal domains, *Science* **291**, 1289–1292).

Furthermore, over half of the genes are contained in T-bands, which represent only 15% of all bands. The combination of this result with the ideograms makes it is possible to obtain a rough picture of the gene distribution over each chromosome.

The base compositions of G-, R-, and T-bands are very different from each other: R-bands are richer in GC content than G-bands, and the 27% GC-richest R-bands correspond almost perfectly to the T-bands. In the context of the previous discussion, this fact suggests that the gene density may be related to the local compositional pattern of the DNA sequence, and establishes a connection between cytogenetic observations and molecular analysis.

2.2 Gene Distribution versus Sequence Composition

2.2.1 Uneven Distribution of GC Content Over the Genome

More than 30 years ago, ultracentrifugation experiments based on the use of sequence-specific ligands, such as silver ions, were performed to achieve high-resolution DNA fractionation. These experiments led to the discovery of the striking compositional heterogeneity in the nucleotide composition of human DNA. Specifically, it was found that the distribution of the GC content over the whole genome is far from uniform, since there is a substantial variation in average GC content among large DNA fragments.

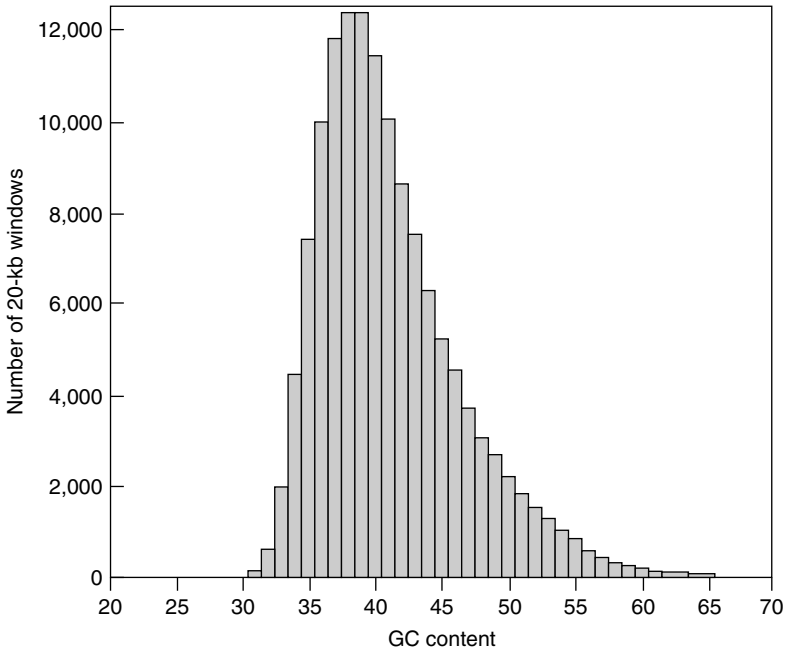

Fig. 4 GC content histogram obtained from the human genome draft (from IHGSC, *Nature* **409**, 2001).

The recent publication of the human genome confirms the uneven GC content distribution in a direct and global manner. Figure 4 shows the GC content histogram obtained from the human genome drafts using 20-kb windows. The figure confirms that local GC content undergoes long-range excursions from its genome-wide average of 41%. Recently, Pavlicek et al. obtained a compositional map of the human chromosomes by scanning the human genome sequence with a 100 Kb moving window. The map shows the large proportion of the genome characterized by long-stretch fragments with low GC content. The regions of GC content greater than 46% constitute only 12.5% of the whole-genome sequence. It is also obvious from the map that the GC content distribution is chromosome specific.

2.2.2 **Isochores**

Bernardi et al. proposed that the long-range variation in GC content reflects that the human genome is a mosaic of isochores, defined as long DNA segments (greater than 300 kb on average) that are characterized by a fair compositional homogeneity (above a 3-kb size level). Isochores in the human genome have been classified into five different families, depending on their percentage in GC compositions. Families L1 and L2 have a GC content lower than the human genome average, specifically in the range $<37\%$ for family L1 and 37 to 42% for family L2. The combination of both families makes up 62.5% of the human genome. A higher GC content than the average is observed in families H1, H2, and H3, which cover the ranges 42 to 46%, 46 to 52% and $>52\%$, and constitute 25, 8.3, and

4.2% of the human genome respectively. Implicit in the isochore definition is the idea that the large-scale GC compositional heterogeneity is discrete or discontinuous, with abrupt changes from higher to lower (or vice versa) GC levels.

Different methods have been applied to determine the isochore families to which human genes belong. All these studies suggest a very nonuniform distribution of genes throughout isochore families: Almost 30% of all human genes reside in the roughly 4% of the genome that belongs to the GC-richest family, H3; in comparison, DNA fragments in families L1 and L2 have much lower gene density, which is less than one-sixth of that of H3.

The relationship between GC content and gene richness has been addressed quantitatively by Mouchiroud et al., who reported a direct positive linear relationship between the GC_3 values (GC levels of third codon positions) of coding sequences and the GC levels of the DNA regions in which they are embedded. This correlation permits the positioning of the distribution profile of coding sequences relative to that of DNA fragments. Consequently, it makes it possible to estimate the relative gene density with respect to different GC contents. In the work of Bernardi et al., this relative gene concentration was calculated by dividing the percentage of genes located in a given GC_3 interval by the percentage of DNA located in the corresponding GC range. With the availability of the draft human genome sequence, the gene density can be estimated directly. Figure 5 presents the gene density as a function of the GC content level, estimated by aligning 9315 known genes on the draft human genome. The results are similar to the earlier estimates, and show the high nonuniformity of the gene distribution in the human genome. Notice that the gene density increases from a very low average level in GC-poor regions to a much higher level in GC-rich regions.

2.2.3 Gene Properties versus GC Content

According to the slope change in gene concentration at the boundary between isochore families H1 and H2 (shown in Fig. 5), Bernardi et al. defined two ''gene spaces'' in the human genome: the ''genome core'' and the ''empty space.'' The ''genome core'' consists of the DNA fragments belonging to isochore families H2 and H3. Although it only represents around 12% of the genome, it embeds more than half of the human genes. The other 88% of the genome has a very low gene density (one gene per 50–150 kb) and therefore is referred to as the ''empty space'' or the ''empty quarter'' (from the classical name of the Arabian desert). This division into core and empty spaces is also validated by other observations, such as (1) the similarity of the gene concentrations in each space; (2) the similarity of the heptanucleotide comprising the AUG initiation codon of human genes observed in L/H1 and H2/H3 isochores respectively, and (3) the identical chromosomal distribution of H2 and H3 isochores.

As indicated before, the compositional pattern of coding sequences is directly related to that of their embedding isochores. Therefore, it is expected that genes in the genome core should have a relative high GC content, while this content should be low for those genes in the empty space. Several studies have confirmed these expectations. Besides the compositional difference, the gene structures in the two spaces are significantly different. Interestingly, long genes are scarce in the core genome and more frequent in the empty quarter. A primary reason for this

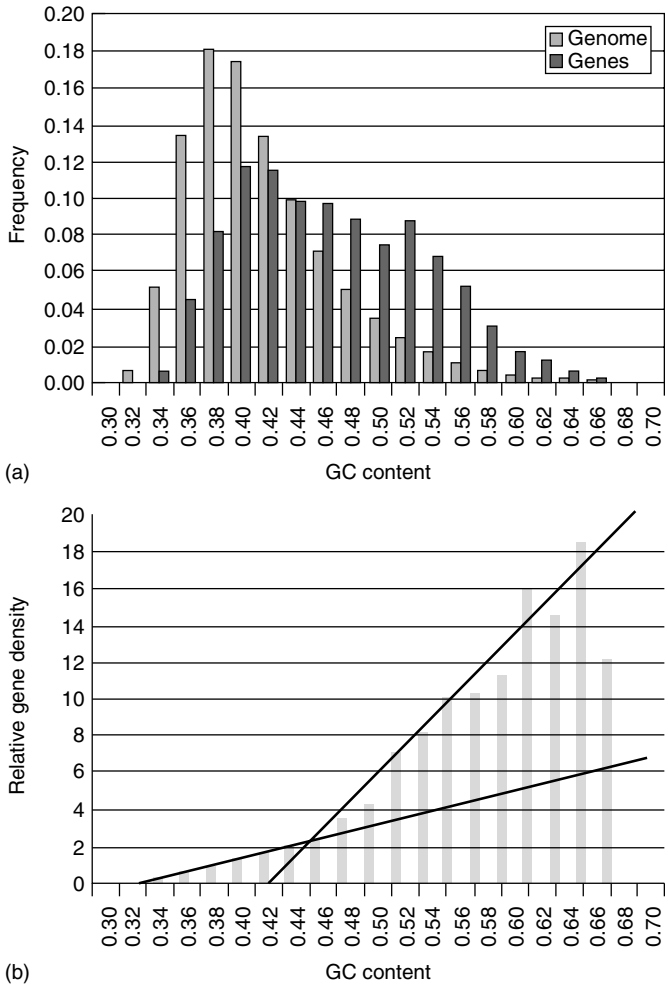

Fig. 5 (a) GC content distribution in 9315 known genes and in the whole genome. (b) Gene density as a function of GC content, obtained by taking the ratio of the data in (a). Values are less accurate at higher GC levels because the denominator is small. The two slopes represented here are associated to the gene core and empty space (from IHGSC, *Nature* **409**, 2001 and *Bernardi* et al, *Gene* **276**, 2001, see original papers for details).

length difference is the fluctuation in intron sizes, which, in the empty quarter are on average three times longer than in the genome core. In contrast, coding properties such as exon length or number of exons in a gene, are not so dependent on GC content. This is corroborated in Fig. 6, which shows the dependence of the mean values of exon and intron lengths with respect to the GC content. As shown in the figure, the intron size decreases as a function of local GC content, with a

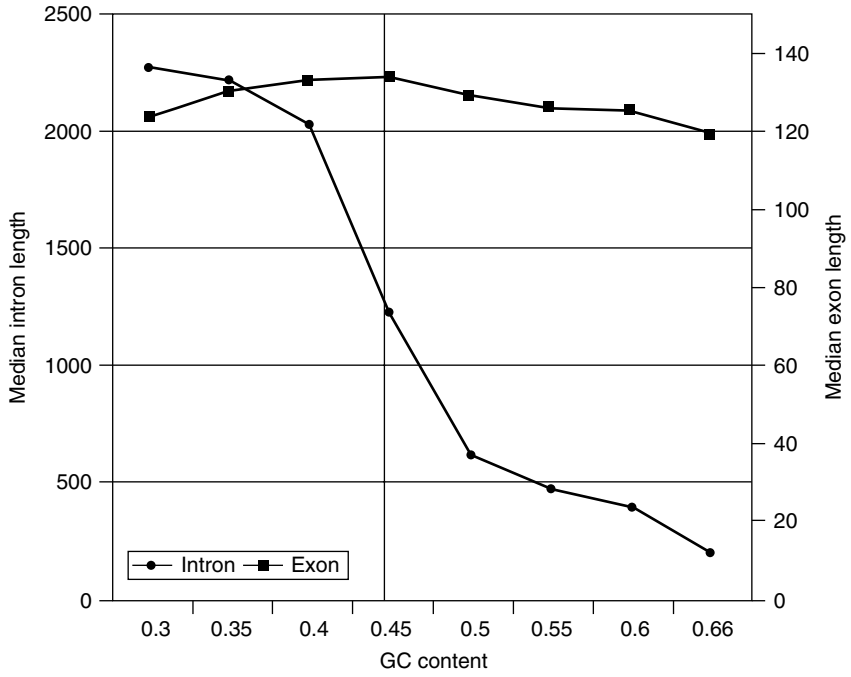

Fig. 6 Dependence of the exon and intron average length on the GC content (from IHGSC, *Nature* **409**, 860–921, 2001, see original paper for details).

sharp transition occurring at ~45% GC, in agreement with the boundary between the genome core and the empty quarter.

Different efforts have been carried out to localize DNA fragments with different GC-richness on human metaphase chromosomes. The results support that the two gene spaces are characterized by different structural and functional properties. GC-poor isochores are located in G-bands and in $H3^-$ R-bands (in which H3 isochores are not detected), which generally exhibit a closed chromatin structure. On the other hand, the chromosomal localization of the GC-richest isochore family (H3) corresponds to T-bands. Moreover, since isochore families are unevenly distributed over the chromosomes, some chromosomes (17, 19, 22) have a very high percentage of genome core fragments, whereas other ones (4, 13, 15, 18, X, and Y) have a very small percentage or no genome core segments at all. The explanation for such an uneven distribution is still unclear.

2.2.4 Evolutionary Hypothesis About Isochores

As explained in previous sections, a correlation is evident between %GC content and the gene density of a chromosomal domain. One of the questions raised by this distribution is which one is under the greatest selective pressure: does the %GC content of a chromosomal domain control the number of genes located within that domain or does the clustering of genes into local domains determine the %GC content? The basic question being asked is at what level does natural selection operate

to produce such clearly demonstrable isochore domains in the human genome. Although this is a simple question, its answer is buried under the complexity of separating gene function from genome structure. We know that in coding domains there is a codon bias toward GC dinucleotides in warm-blooded vertebrates that result in a higher proportion of hydrophobic and amphipathic amino acid residues in proteins. One of the consequences of maintaining protein structure at higher body temperatures (37 °C) may be an increased need for hydrophobic interactions, thus resulting in a strong selective pressure for greater %GC representation in coding domains. However, the regulation of gene expression events appears to be just as critically controlled by %GC composition. Large-scale alterations in chromosome structure related to GC hydrogen bonding in double-stranded DNA can alter the accessibility of expression regulators to promoter domains.

It is difficult to isolate the impact that nucleotide sequence has on the selective fitness of an organism because a gene sequence is operational at two levels: (1) gene level function, and (2) structural conformation of local chromosomal domains. The difficulty of dealing with the concept of isochores is that this phenomenological observation crosses these two functional boundaries. Identifying the most proximal cause of such sequence anomalies (% frequencies showing such large departures from a random frequency distribution) is difficult because of the interdependence of structure and function.

2.2.5 Recent Discussions About the Isochore Concept

In this chapter, we have presented the standard definition of the isochore concept. However, the plausibility of the ''isochore'' concept has been questioned in several recent papers. Most of the concerns focus on the definition of ''compositional homogeneity'' – which some recent papers interpret as relative to random sequences – on the capability of ultracentrifugation experiments to define intrasequence heterogeneity, and on the fraction of the human genome to which the isochore concept applies. Some of these concerns have been addressed by Bernardi and Clay. Other authors point to the fact that isochore families were not originally defined from sequence data, but from ultracentrifugation experiments that resulted in 5 (after a somewhat arbitrary reduction from 13) major overlapping Gaussian distributions of absorbance, each one associated with a distribution of GC content. Therefore, because of the overlapping, a DNA fragment with a given GC content could correspond to different isochore families, which is a drawback to the definition of isochores based only on the sequence data. In order to overcome this problem, the boundaries (in CG content) among isochore families can be defined in such a way that they do not overlap, as we directly did when we introduced isochores. However, this definition is different from the original one.

The concepts of homogeneity and heterogeneity are largely subjective, and therefore much more research is necessary to develop better methods to perform segmentation of the genome into regions of different GC content. However, the existence of GC-rich and GC-poor regions in the human genome has now been fully corroborated by the draft sequences. Moreover, many studies have indicated an interesting correlation between GC content domains and various biological properties, including transcriptional regulation, local DNA replication,

patterns of codon usage, and the posttranscriptional processing of mRNA. Although much more work is still necessary before reaching a clear conclusion, the study of the distribution of guanidine and cytidine nucleotides will be a primary route to a better understanding of the gene distribution in the human genome.

3 Microscale Structure

In Sect. 1, we saw that the most recent estimates predict that the human genome contains a number of genes in a 30 000 to 40 000 range, a surprisingly small amount if we consider that much less complex organisms such as *Arabidopsis* and *Caenorhabditis* are also supposed to have a similar number of genes. As a first attempt to explain this fact, it seems intuitive to think that we may need to look outside of the coding sequences for the mechanisms that generate the complexities inherent in the human development. This intuition has been confirmed by an increasing amount of recent work in the literature, which suggests that the explanation is buried in introns and intergenetic regions, once referred to as ''junk sequence.'' An important piece of supporting evidence is the obvious correlation between the GC levels of coding sequences and their context DNA fragments in which they are embedded. The study of the patterns in these noncoding regions may provide hints on the gene distribution over the genome.

3.1 Gene Model

Human genes are characterized by long introns, which on average constitute more than 90% of a gene. The median of the intron sizes (~1000 bp) is about 8 times the median of internal exon sizes. Moreover, the distributions of gene size, intron size, and the number of introns in a gene present significant fluctuations, much higher than those of exons. This is shown in Fig. 7, where the exon and intron size distributions are shown for the human, the worm, and the fly. It is interesting to note that the exon distribution is very similar in the three species, while the intron distributions (and therefore the overall gene size distribution) presents a much higher difference among the three species, with the human distribution being the one with greater variability. Another interesting observation is the dependence between intron sizes and the local GC-level: on average, GC-rich regions show a scarcity of long introns, while the median intron size in GC-poor regions is about twice that encountered in the whole genome. This special pattern is believed to be related to the splicing mechanism. For example, Bernardi suggests that long introns in the gene-poor fragment may facilitate alternative splicing in tissue dependent genes.

Despite the controversy over the exact nature of isochores (whether phenomenological or functional), it is clear that the most prominent feature of protein-coding genes is their higher than average GC nucleotide (guanidine and cytidine) compositions. Majewski has compiled sequence analysis data for 10 858 identified human genes into a ''model'' gene composed of

- 2000 bp promoter region
- first exon (250 bp, mostly nontranslated)
- first intron (just 500 bp on the 5′ and 3′ ends)

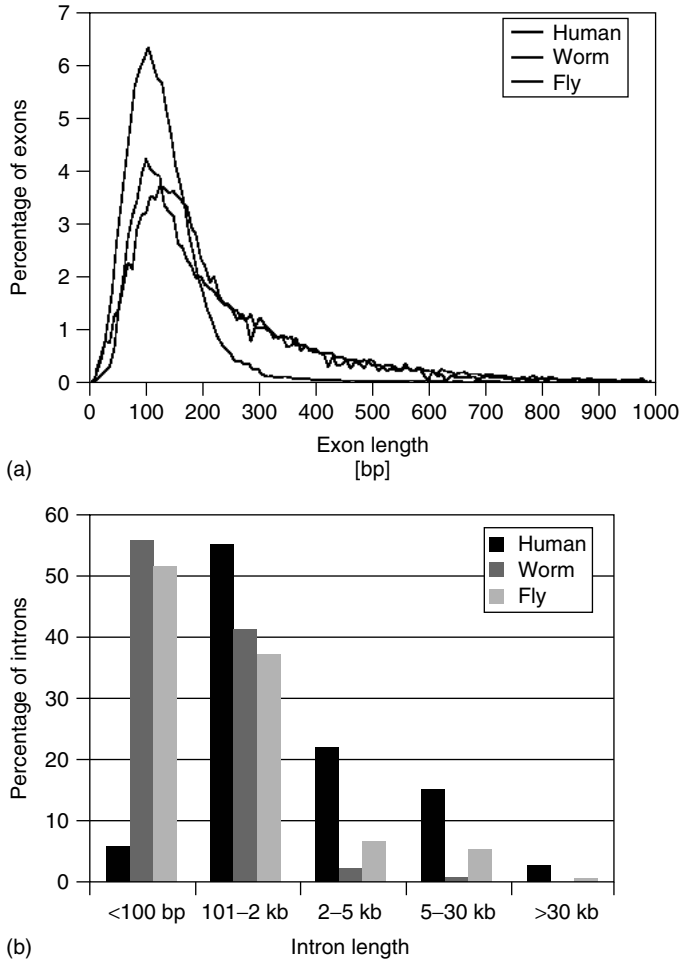

Fig. 7 Size distributions of exons, introns, and short introns for worm, fly, and human genomes (from IHGSC, *Nature* **409**, 860–921, 2001, see original paper for details).

- internal exon (500 bp)
- internal intron (just 500 bp on the 5′ and 3′ ends)
- terminal exon (500 bp)
- termination domain

In most vertebrates, exons and introns can be much larger than 1000 bp total. For this sequence analysis, the calculation of frequency distributions for each of these domains was executed by examining nucleotides at the same sequence positions relative to the splice sites and/or boundaries known to exist in the 10 000 + genes used for this study. Each of the essential gene elements categorized above have been condensed into a grand average in terms of nucleotide composition (Fig. 8).

Although genes have higher GC compositions, the distribution of G and C

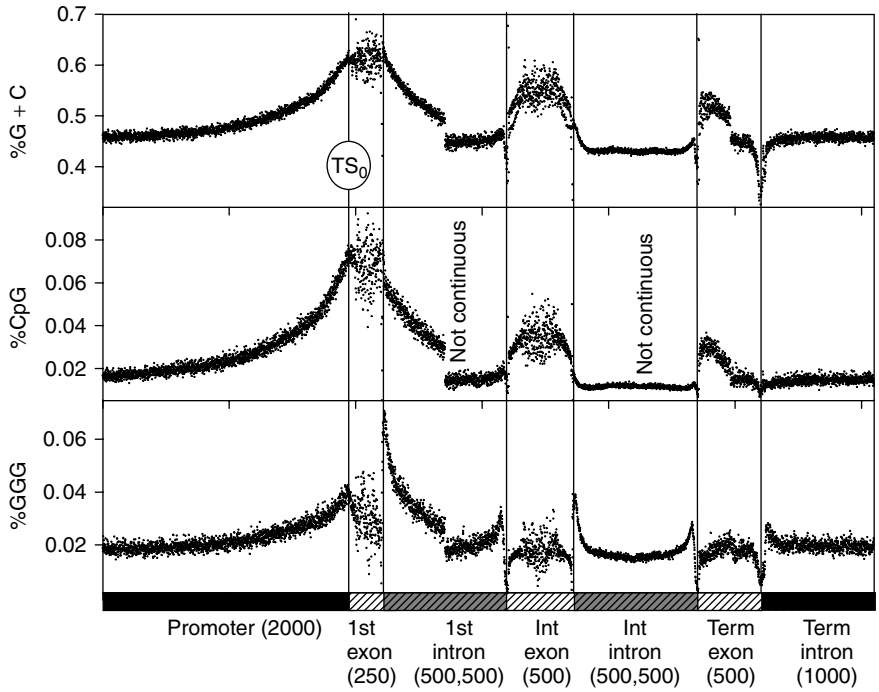

Fig. 8 The distribution of sequence elements within an archetypal model gene are shown for a composite of 10 858 currently known human genes (Majewski and Ott 2002). Gene positions were aligned relative to the transcriptional start site (TS_0) and nucleotide frequencies were then averaged by relative position to determine the frequency of (a) % composition of cytidine and guanidine nucleotides, (b) 'CpG' dinucleotide motifs, and (c) ''GGG'' trinucleotide repeats. The sequence composition evidences several striking patterns in terms of the distribution of G and C nucleotides across all described genes (int = internal; term = terminal). [These distributions are replotted from the original Fig. 5 of Majewski, J. and Ott, J. (2002) Distribution and characterization of regulatory elements in the human genome, *Genome Res.* **12**, 1827–1836 using the original data kindly provided by J. Majewski.]

nucleotide frequencies is heterogeneous, with distinct intragenic locales. Outside of a gene domain, the GC content is between 42 and 45%. As one moves (5′ to 3′) into the promoter domain (2000 bp from the first exon) the GC content steadily increases to upwards of 60% at the beginning of the first exon (transcription start site, TS_0). The first exon has an average GC composition of 55 to 60% without any spatial differentiation. Most interestingly, at the splice junction between the first exon and the first intron there is a sudden increase in the GC composition. The 5′ end of the first intron (the splice junction with the first exon) has a GC distribution of nearly 65%. This frequency then rapidly declines further into the intron, but exhibits another rise as one approaches the 3′ splice junction with the first internal exon, as shown in Fig. 8.

The internal exons exhibit an interesting feature with a peak in GC content between 100 to 150 bp away from the splice

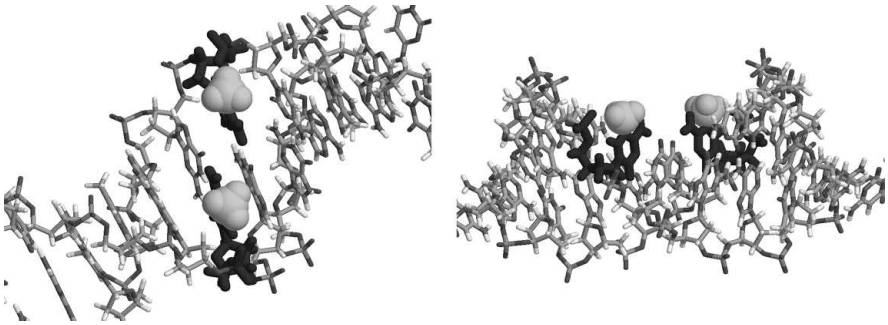
junction on either end, and then a decline in GC frequency as the splice site is approached. The internal introns evidence an opposite distribution with peaks in GC frequencies right at the splice junctions, and then declines to average levels roughly 200 bp away from the junction. The presence of such significant spatial shifts in nucleotide frequencies (especially at boundary junctions) is suggestive of functional mechanisms for regulating gene transcription and RNA posttranscriptional processing. However, it is unlikely that the mere sequence composition of a gene element provides a specific enough mechanism for exerting fine-scale regulatory controls. Rather, spatial shifts in GC distributions are more likely to reflect changes in the distribution of specific regulatory motifs that have higher proportions of GC nucleotides.

The archetypical gene model provides a unique look at how human genes are structured. The most significant feature in terms of the potential regulation of gene expression rates is the distance, both upstream and downstream from the TS_0 site, for which significant biases for the presence of GC motifs can be found. There are several regulatory motifs in this wide domain whose mechanistic actions to control gene transcription events are determined by cytosine and guanidine nucleotides, such as CpG and GGG motif. The potential regulatory domain for direct transcriptional control over a single gene locus comprises a ~2000 bp window around the TS_0. This domain results in a large number of potential regulatory interactions among the special motif distributions; however, regulatory regions can exist much farther upstream. This range of potential control states is thus likely to establish the high recombinatorial repertoire in potential expression patterns that is essential for the evolution of complex network interactions.

3.2 CpG Islands

"CpG islands" (CGIs) are one of the most prominent regulatory motifs in the human genome. The name refers to a simple dinucleotide motif of a cytidine and guanidine (5′-C-p-G-3′) within a GC-rich chromosomal domain. The frequency of CpG dinucleotides in the human genome is much less than expected, as a result of a methylation/mutation process. Generally, about 60 to 90% of the CpG sequences within a genome are methylated. DNA methylation is a reaction, specific to cytosines in CpG dinucleotides, that transfers a methyl group from *S*-adenosylmethionine to the C5 position of cytosine. Methylated cytosines have a high mutation rate to thymines (CpG to TpG), which has been confirmed by many studies on DNA polymorphism or genetic diseases. This process, known as GC suppression, leads to an overall reduction in the frequency of GC content to about 41% of all nucleotides and a further reduction in the frequency of CpG dinucleotides to about a quarter of their expected frequency. CpG islands (those C–G motifs in GC-rich domains) are primarily unmethylated and are the exception to CpG underrepresentation in the genome.

CpG islands make up 1 to 2% of the DNA sequence. They are of great importance because the cytidine base can be methylated such that the methyl group extends upwards into the major groove of the DNA helix (Fig. 9). The intrusion of these polar methyl groups essentially disrupts the potential interactions between the local nucleotide bases and transcriptional regulators in this domain by altering the



(a) (b)

Fig. 9 Three-dimensional structure models for the methylation site in a CpG motif; (a) top view perpendicular to the major groove, (b) side view parallel to the major groove. The 5-methyl-cytidine residues are drawn in the dark wireframe representation, the methyl group atoms are shown with Van der Walls atomic radii as gray spheres. The primary impact of the methylation appears to be a redistribution of charges around the C–G hydrogen bonding. The nonpolar methyl group is adjacent to the amino ($-NH_2$) group that would establish one of three hydrogen bonds with the complementary G-residue hydroxyl group (coordinate data from PDB ref# 1IG4).

local charge distribution. Usually, both the (+) strand motif and the complementary (−) strand motif cytidines are methylated (m5C) to increase the density of methyl groups within a small area (see Fig. 9):

$$5'\text{–C5m–G–}3'$$

$$3'\text{–G–m5C–}5'$$

This provides an effective blocking mechanism to ''silence'' regions of DNA from being transcribed and is one of the most active areas of current research into epigenetic mechanisms of gene regulation.

CGIs commonly occur in the promoter domains of functional genes. Overall, this pattern suggests that the majority of the methylated CpG motifs play a role in gene silencing (blocking transcription of noncoding regions, repetitive DNA elements, transposable elements, pseudogenes, etc.). But in active promoter domains, the methylation states of CpG motifs are not fixed such that changes in methylation can be used for up-and-down regulation of transcriptional activities at a specific gene locus.

An attractive property of CGIs is their significant structural difference from the rest of the genome. In the work of Gardiner–Garden and Frommer, CGIs were formally defined as sequences greater than 200 bp in length, with a GC content greater than 0.5, and with an observed to expected GC content ratio (CpG_{obs}/CpG_{exp}), greater than 0.6. This definition has been widely used in later studies. Recent work has suggested more specific structures for CGIs, especially for those potentially corresponding to promoter regions. This makes it practical to search for CGIs using computing tools. In the work from the International Human Genome Sequencing Consortium, a computer program was implemented to identify CpG islands and 28 890 CGIs were found in the draft human genome sequence with repeat regions masked. The count of 28 890 CGIs is reasonably close to previous estimates

of about 35 000, which were obtained by experimental methods. The convenience of CGIs searching has led to effective approaches for gene estimation. In 2000, Grunau et al. determined features that discriminate the promoter-associated and promoter-nonassociated CpG islands and used them for large-scale human promoter mapping.

As shown in Fig. 10, the density of CpG islands shows important variations in different chromosomes and correlates positively with estimates of the gene density. Chromosome Y is the one presenting the lowest density, with 2.9 islands per Mb. On the opposite extreme, chromosome 19 presents a density of 43 islands per Mb. The average for all the genomes is 10.5 islands per Mb, with most of the chromosomes having 5 to 15 islands per Mb. Similar trends are observed when the percentage of nucleotides contained in CpG islands is considered.

The coherent distribution of CpG islands within the model gene demonstrates the general feature that these motif elements comprise for all human genes (Fig. 8). There is a fourfold increase in CpG frequency in the promoter domain as one moves 5′ to 3′ from −2000 bp down to the first exon (0 bp at transcriptional start site). The high frequency occurrence of CpG islands is maintained through the first exon (+250 bp) and into the first intron. This distribution on either side of the first exon boundary suggests a potential regulatory influence of CpG methylation patterns extending from −1000 bp upstream of the TS_0, across the first exon (0–250), and then 500 bp into the first intron.

The position of CpG islands at the TS_0 appears to be a crucial mechanism for temporal and spatial regulation of gene expression rates. In Fig. 11, we have summarized gene expression data for 24 tissue types from both adults and embryos (orthologs in mouse embryos) on the basis of the presence/absence of a CpG island at the TS_0 site. In human adult tissues, there is a significant trend for genes exhibiting tissue-specific expression patterns to have a CpG island at the

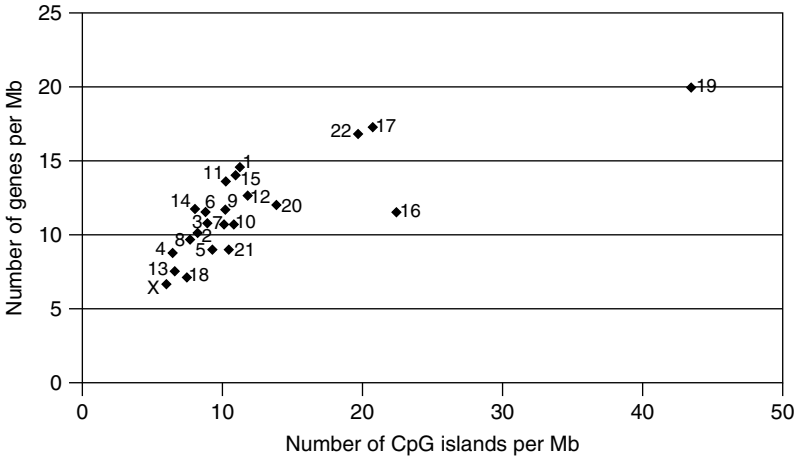


Fig. 10 Number of CpG islands per Mb versus number of genes per Mb (from IHGSC, *Nature* **409**, 860–921, 2001, see original paper for details).

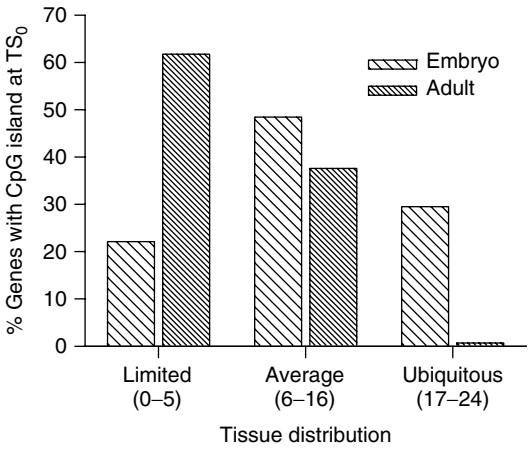

Fig. 11 Frequency of genes with CpG-island regulatory elements in their transcriptional start domains. Genes are separated into three categories depending the number of tissues that express those genes (collated expression data from 24 tissue types). Expression categories range from "limited" (expression in less than 5 tissue types) to ubiquitous (expression in more than 17 tissue types). Regulation of gene expression in adult tissues clearly demonstrates a frequency relationship between tissue-specificity and the occurrence of CpG islands at the TS_0 (data replotted from Ponger, L., et al. (2001) Determinants of CpG islands: Expression in early embryo and isochore structure, *Genome Res.* **11**, 1854–1860).

TS_0 (62%), in contrast to genes that are ubiquitously expressed (housekeeping genes) where only 0.7% exhibited a TS_0 CpG motif (Fig. 11). This pattern strongly indicates that CpG methylation may be one of the primary mechanisms by which tissue-specific expression patterns in adults are regulated. The pattern of CpG distributions in embryonic gene regulation does not appear to be correlated with tissue-specific expression.

3.3 GGG Trinucleotide

Another important regulatory motif is the "GGG" trinucleotide, which will obviously be more prevalent in GC-rich (isochore) domains. These motifs have been shown to be overrepresented within introns and have been implicated to function in regulating RNA splicing during posttranscriptional processing. In the archetypal model gene, the distribution of GGG trinucleotides shows a predominant location at the 5′ ends of intronic (noncoding) domains. This distribution supports the hypothesis that these motifs are critical control components of RNA posttranscriptional processing by the spliceosome protein complex. Also, it is quite significant that the GGG frequency is much lower than expected near the TS_0 and across the first exon. This deficiency suggests that the GGG motif does not commonly play a role in the regulation of gene expression rates; however, a few examples of GGG-mediated gene regulation do exist. It is important to keep in mind that the archetypal model just represents an overall average nucleotide distribution.

A related motif with less known function is the "CCC" trinucleotide. Splicing control elements (SCEs) can only process nucleotide motifs on the coding (transcribed) strand so that "GGG" and "CCC" distributions are not functionally reflexive (simple reverse complements of each other). The frequency of CCC motifs on the coding strand must present a distinct regulatory structure for SCE recognition, and although the representation of CCC motifs is not as significant in the archetypal model gene as are the GGG motifs, they evidence the same prominence in intron borders and scarcity in the promoter and

first exon domains. Consequently, the observed increase in %GC content flanking the TS_0 can primarily be attributed to an increase in the frequency of CpG islands, and not the distribution of trinucleotide repeats of cytidine or guanidine.

3.4 Pseudogene Distributions

Pseudogenes are a subclass of genes in which the coding domain is no longer subjected to selection forces acting on cellular fitness. There are two primary routes of pseudogene formation: (1) duplication of a chromosomal region, and (2) reverse transcription of an mRNA molecule into cDNA and consequent reintegration of that processed transcript back into the genome. In either case, the end result is that two copies of an operative gene now exist in the genome, one of which will continue to function under the selective pressures it has been adapted for, and the other is now independent of any selection pressures (i.e. it does not impact the cellular fitness of an organism if the copy is expressed or not expressed, because the original operative gene is continuing its function). The two cases are easily distinguished because with a gene domain duplication, all the noncoding regulatory regions are preserved in the copy (promoter, introns, terminal domain), while in the reverse transcription of mRNA (retropseudogene), the mRNA transcript has been processed such that the promoter, introns, and much of the terminal domain have been removed, or modified. For reverse-transcribed pseudogenes, they must become integrated back into the genome downstream from an active promoter for any possibility of transcriptional activity.

Pseudogenes can be actively transcribed and in that respect are truly ''genes'' other than the fact that there is no selective pressure on them to actually do anything useful. On chromosomes 21 and 22 (the most thoroughly studied to date), a total of 454 pseudogenes have been identified, and estimates based on the draft human genome to date suggest that there will be between 23 000 and 33 000 pseudogenes in total. (http://bioinfo.mbb.yale.edu/genome/pseudogene/) Thus, pseudogenes are likely to play an important role in evolution by allowing operative genes to obtain new functions without immediate detrimental effects to an organism. However, most pseudogenes appear to be destined for genomic oblivion once they are formed. Without a strong selection on function, random drift in the nucleotide sequence rapidly (on an evolutionary timescale) can introduce premature termination signals or frameshifts that result in nonfunctional mRNA transcripts. There are very few documented cases of pseudogenes evolving into new operative genes.

The documentation of pseudogenes in a genome is not easy. It is likely that there are numerous operative genes in the human genome that have a pseudogene origin. Because most genes themselves are located in GC isochore domains, they have higher than average %GC compositions. Once a pseudogene is formed, random mutational drift will tend to reduce the %GC composition toward the genome average. If the pseudogene adapts to provide a new function, its phylogenetic sequence affinity can be obscured by the shift in nucleotide composition away from its ancestral operative gene. Because only ~1.5% of the human genome is directly involved in coding for protein sequences, there is a large background of DNA for many recombinatorial possibilities to arise from rearranging DNA. A recent study has been able to identify the

incorporation of several mitochondrial genes into the human genome, suggesting a new route for pseudogene incorporation when eggs are fertilized by sperm. As our understanding of these processes increases, it is likely that we will be able to develop the computational tools to more fully identify operative-pseudogene relationships.

3.5 Transposable Elements

There are sequence elements in the genome that are very efficient at duplicating and moving their local DNA domains. These transposable elements (TEs) were originally described as parasitic DNA, because of their ability to self-replicate unchecked within a genome environment. However, our understanding of their role in genome structuring is just beginning to identify them as absolutely necessary or at least mutualistic elements. At present we know little about their molecular mechanism of operation, and are left to only speculate on the potential importance of their role in genome evolution. As discussed in the previous section on pseudogenes, the ability to create copies of genes is an important mechanism for either deriving novel functions from existing proteins, or to give existing proteins different patterns of expression. TEs appear to be the primary vehicle by which genomic material is shuffled around into alternative recombinations as a natural experiment resulting in new genes and expression patterns. ''NEW'' is not necessarily better and these alterations may or may not be selectively advantageous. However, such rearrangements can provide a greater molecular diversity within an organism for selection to then act upon. A large body of literature on TEs exists, particularly in terms of structure and function in *Drosophila*, and the reader should consult these resources.

4 Metascale Integration

The first pivotal study of functional genomics lead to Jacob & Monod's seminal description of the *Lac* operon in *Escherichia coli*. Their summary description of the ''one gene equals one protein'' organization of DNA set the stage for the next three decades of genomic research focusing on linear, direct models of gene interactions. This approach worked well for the single-target cloning strategies that were implemented in the 1970s to late 1980s. However, in the 1990s, as high-throughput technologies were developed, the collection of gigabytes of gene expression data opened up new avenues for approaching the functional organization of a genome as a three-dimensional structure, that is, one in which the genetic code was not just operative in a long, one-dimensional array of four nucleotides. It is now clearly evident that gene location within a chromosomal domain has a significant impact on transcriptional regulation.

The interaction between genes, their protein products and their chromosomal locations are now routinely considered in network organizations of ''connectivity.'' Long gone (in terms of the volume of literature that has appeared in the last five years) is the focus of identifying linked companion genes in operon-like, downstream–upstream units. Even the paradigm of ''one gene equals one protein'' needs qualification as alternative splicing, bidirectional coding and post-transcriptional mRNA processing has lead us to realize that single coding domains

may produce several proteins, given the multiple mechanisms that are involved between the initiation of gene transcription and the folding of a final protein product.

Given the importance of describing how genes are ''connected,'' there is considerable attention being focused on identifying the mechanistic relationships that may exist between coordinated patterns of gene expression (i.e. network associations) and the physical mapping of those transcriptionally linked genes. With the current estimate of only ~35 000 genes in the human genome, there is strong support for the idea that interactive mechanisms between chromosomal locations and mRNA processing are just as important in determining the physiological ''fitness'' of genes (e.g. their contribution to organismal survival) as are primary nucleotide sequences.

In this section, we will cover the essential relationships between expression connectivity and physical location, with the goal of describing the potential links between gene location, function, and evolution.

4.1 Associative Expression Networks

The field of proteomics has established the clear necessity of describing the coordination between gene expression rates and functional protein activities. This includes a focus on describing the multiple interactions between genes and/or proteins in an environmental context. Correlating single gene expression events (mRNA transcription) with protein-level functioning (specific activities) has been relatively unfruitful, with many variations in gene expression levels not reflected by corresponding changes in their protein pools. We now know that even for such ''housekeeping'' proteins as lactate dehydrogenase and Na^+- and K^+-ATPase, levels of gene expression and levels of functional protein activity are usually not directly correlated. The regulation of gene expression and protein activities appears to be coordinated at a higher level of physiological organization. We call this organizational structure a ''network'' to reflect the many parallel connections between gene expression events and protein activity levels.

Gene expression experiments, such as microarrays and gene chips, are widely used to identify genes that appear to function together because of their coordinated expression behavior. However, the best strategy for identifying such ''coordination'' in expression data is open for debate. The most general approach adopted has been one of paired correlation analysis to produce gene clusters associated by expression patterns. To extract finer-scale interactions between genetic components in terms of induction, repression, modulation, and coordination requires a more concerted analytical scheme to deduce network connectivities between gene or protein members. This level of analysis involves establishing an interactive structure or network around which the data can be quantitatively assessed. Both Boolean and Bayesian network models are currently employed for resolving finer features of interactions and dependencies in multivariate expression data.

One of the key components to describing complex network interactions is designing experimental manipulations of the expression system that will provide a wide range of expression data. The strategy is described as ''extreme pathway'' modeling or ''perturbed expression'' profiling. The idea is to generate as many potential variants of expression of different targets due to treatment stressors or transgenic manipulations (knockouts, overexpression).

Gene and protein interactions are then assessed across this diversity of expression patterns. In general, genetic systems now appear to be organized into ''small-world'' networks, which means they have discrete subnets or local communities that respond coordinately. This observation can simplify an interactive network analysis by limiting the size of the subnet units to be considered. Complete network datasets are cumbersome and suffer from statistical insensitivity because of the large numbers of component members. Isolating smaller subnet units in perturbed expression profiles can lead to the identification of statistically robust, local-community interactions.

An awareness of the adaptive versatility of subnet structuring is rapidly developing in environmental genomics. Simple connections between densely integrated subnets allow for (1) a large degree of flexibility in coordinating the regulation of biochemical and cellular activities, (2) provide a large recombinatorial mechanism for the *de novo* appearance of new functionalities, and (3) are robust in terms of their internal buffering capacity against external inputs. Subnet rewiring is potentially one of the dominant mechanisms of epigenetic interactions impacting species' environmental adaptations and evolution. Using high-order structure analyses to relate complex expression data (microarrays) to cellular function has a large potential to provide new insights into how genomic-level interactions are structured in adaptive network associations.

4.2 Functional Coordination and Physical Mapping

Unfortunately, one of the fundamental, guiding principles of expression network analyses is that coordinately transcribed genes will be functionally related. This assumption is based on the assumption that gene transcription rates are independent and that equivalent patterns of expression between two genes are thus indicative of parallel promoter activities. However, recent studies that have mapped transcriptional activities (from microarray and serial analysis of gene expression (SAGE) analyses) to the corresponding chromosomal gene locations have demonstrated that transcriptionally active domains are heterogeneously distributed throughout the genomes of humans, flies, nematodes, and yeasts. These domains are a very significant feature of mRNA expression dynamics because genes that are closely located on chromosomes are likely to evidence ''correlated'' expression patterns simply because of their physical location, rather than any functional association.

A Human Transcriptome Map (HTM) has been assembled by the integration of several independent databases from SAGE profile data, the draft human genome, and chromosomal maps. This HTM is accessible through a web portal based at the Amsterdam Medical Center, University of Amsterdam. (http://bioinfo.amc.uva.nl/HTM-bin/index.cgi/) Although the statistical determination of regions of increased gene expression (RIDGE) domains needs further exploration, the basic observation of heterogeneous distributions of transcriptional activity for 2.5×10^6 SAGE transcript tags across 12 tissues types is visually evident in the excellent array of web tools the HTM site provides for exploring specific expression locations. On an average, RIDGEs contain between 6 and 30 mapped genes per centiray (genes cR^{-1}) in contrast to the 1 to 2 genes cR^{-1} in domains that are low in transcriptional activity. In addition, RIDGE segment genes evidence average expression levels that are

sevenfold higher than the overall genome average. A rough calculation using gene targets and gene transcription rates would suggest that total transcriptase activity in RIDGEs is between 20 and 200-fold higher than in weakly expressed domains.

The selective mechanism (i.e. the advantage in molecular and biochemical "fitness") for the reason why genes are heterogeneously distributed across chromosomal domains and the reason why transcriptional activities evidence such large spatial differences remains unknown, but certainly not for a lack of speculation. Although there are many logical ideas on the table, the stumbling block is that biological systems are not logical; they do not arise from optimized design principles. Instead, chromosome structure and function have been determined purely by operational efficiency. Logically, the human genome could be as small as ~50 Mb, but operationally, functional competency has required 3.3 Gb, at least at this point in time in the ongoing evolution of the hominid genus (*Homo*).

With this in mind, there appeared to be preliminary support for a hypothesis that tissue-specific patterns of gene expression were coordinated by clustering genes into functional domains in order to unify transcriptional controls. This direct explanation could account for a large component of the variable distribution of genes into distinct, tissue-specific cassettes. However, in a summary comparison of the expression levels of over 11 000 genes from 14 different tissues, Lercher et al. demonstrated that those genes that are tissue-specific in their expression do not cluster together into local domains. To the contrary, their analysis shows that it is the ubiquitous housekeeping genes that do show strong positional clustering within a chromosome. This distribution suggests that the apparent clustering of genes that share high expression rates is primarily a consequence of the local clustering of housekeeping genes, or more generally, genes whose products are necessary in most human cell types.

Although the polytene banding patterns on chromosomes are direct evidence of large-scale spatial heterogeneity in chromosome structure, there does not appear to be any correlation between specific chromosomal structures and transcriptional activity. The expression domains in the fly genome reveal ~200 groups of adjacent genes that have similar patterns of expression across 80 experimental conditions. These groups have 10 to 30 nonrelated genes (in terms of cellular function) covering an average domain size of 100 Kb (range of 20–200 Kb). However, these domains do not evidence any spatial correlations to polytene structure.

The intrachromosome domain model of nuclear organization suggests that genes are more likely to be located at the surface of chromosome territories. In humans and mice, there is substantial evidence to indicate such a differential location of active genes at the surface of chromosomal territories. But the locations of both housekeeping and tissue-specific genes do not appear to be confined to just the peripheral domains of chromosomal territories, indicating that the tight and loose banding of chromatin may not restrict the transcriptional machinery from accessing different locations. There is clearly a near-neighbor effect on the transcription rate of most genes and it is likely that the intercorrelation of gene density and local transcriptional activity influences the gene organization of chromosomes, rather than the activity of individual promoter domains functioning in isolation.

4.3 Physical Colocation and Dislocation

For a better understanding of the distribution of functionally related genes, we have summarized the chromosomal distributions of the genes coding for enzymes involved in the glycolysis and the tricarboxylic acid pathways (TCA) using the Kyoto Encylopedia of Genes and Genomes (Table 1; http://www.genome.ad.jp/kegg/kegg2.html). All human cells are dependent upon the oxidation of glucose via glycolysis and the TCA cycle for generating metabolic energy (ATP and reduced nicotinamide adenine dinucleotide ($NADH,H^+$)). Although these pathways are highly integrated in terms of the production (glycolysis) and utilization (TCA) of acetyl-coenzyme A, the constituent enzymes have very different intracellular locations: glycolysis = cytoplasm; TCA = mitochondria. Thus, one might expect that the transcriptional requirements for maintaining the protein pools in these different cellular locations could serve as a selective force to organize the genes into local domains (i.e. mitchondrial group, etc.). The physical map locations for these genes were obtained from the LocusLink database at the U.S. National Center for Biotechnology Information. (http://www.ncbi.nlm.nih.gov/LocusLink/)

Using the normalized chromosomal ideograms, Fig. 12 traces the sequential order of gene loci that are involved in the catabolism of glucose. Although these

Tab. 1 A serial list of the enzymes involved in glycolysis and the TCA cycle. Chromosomal locations were obtained from the LocusLink database and the loci codes used in Fig. 12 are indicated in the ''map'' column.

EC#	*Enzyme Name*	*Location*	*map*
2.7.1.1	Hexokinase	10q22	a
5.3.1.9	Glucose-P-isomerase	19q13.1	b
2.7.1.11	6-phosphofructokinase	21q22.3	c
4.1.2.13	Fructose-bis-P aldolase	16q22-q24	d
1.2.1.12	GAP-dehydrogenase	12p13	e

3.1.3.11	Fructose-bisphosphatase	9q22.3	v

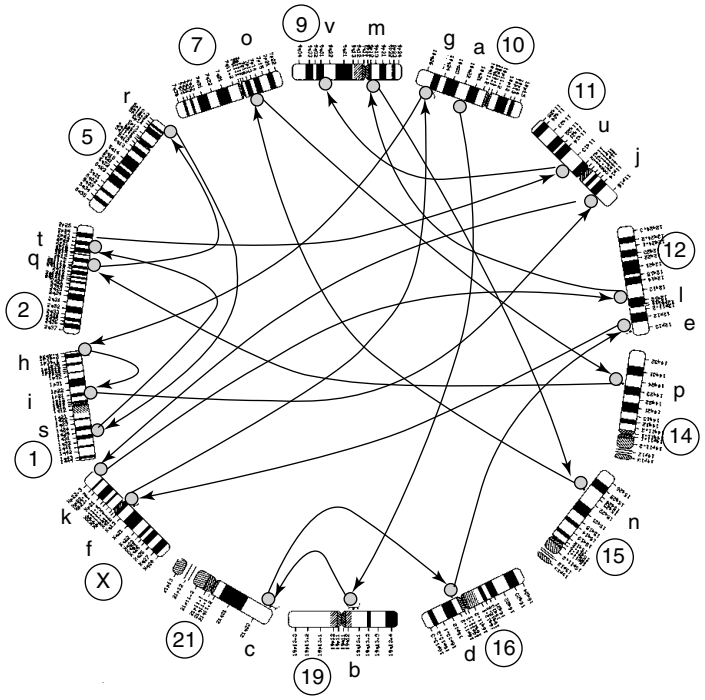

Fig. 12 The chromosomal locations of the gene loci involved in glycolysis and the TCA cycle. Although these metabolic pathways are dominant features in all human cells and are organized into two discrete cellular compartments (cytoplasm and mitochondria), there is no apparent colocalization of these genes within common chromosomal domains.

genes are as fundamental as one can get in terms of housekeeping genes in humans, they are not localized into operational groups of ''glucose metabolism'' or ''mitochondrial locations'' or ''TCA cycle'' cassettes in which their transcription rates could be coordinately controlled.

This result may appear to contradict the positional analysis of Lercher et al. where they conclude that it is the housekeeping genes that do show strong positional clustering within a chromosome. The above analysis of the glucose oxidation housekeeping enzymes (Fig. 12) is meant to illustrate that even though ''housekeeping'' genes appear to be coordinately located, ''housekeeping'' is only an operational definition that could easily apply to more than 80% of the genes expressed in any tissue. Consequently, with so many ''housekeeping'' genes in a genome, and those genes concentrated into domains, there is a high probability that neighboring genes in a location will be ''housekeeping'' even though they may share no functional relationship in terms of their biochemical activities.

A first glance at Fig. 12 begs the question ''is this an organized pathway?'' This is because we think of pathways as linear, chain reactions and anticipate a linear organization in the underlying genetic structure (such as in a *Lac* operon type model). However, in

most ''housekeeping'' pathways, component metabolites are often shared with multiple other metabolic pathways, creating an interactive network association of biochemical activities. Thus, there is no realistic mechanism for all the protein-coding loci of a pathway to be colocated if each gene member of that pathway is also a component in several other biochemical pathways. So the startling pattern evident in Fig. 12 is that the 22 primary genes involved in the glucose oxidation machinery are dislocated across 14 chromosomes. And in no instance are any two sequential protein genes colocated.

4.4 Dynamic Expression Linkages

In looking at the dislocation of genes coding for glycolytic proteins in Fig. 12, we struggle with an inability to understand the design by asking the question ''why?'' Why should functionally related genes be distributed randomly (without apparent pattern) across half of our chromosomes? However, a more direct route for us in terms of deciphering a design mechanism would be to start by trying to answer the question ''why not?'' From this perspective, a list of observations favoring a random distribution can be summarized as follows:

1. Natural selection is operative at the level of phenotype dysfunction. As long as any process (molecular, biochemical, cellular) does not diminish the overall fitness of the organism in its entirety, that trait is selectively neutral (the mechanism of natural selection eliminates individual genotypes with deleterious traits). In terms of gene organization, it makes no difference in selective fitness for an organism if metabolic pathway genes are colocated or not. As long as their expression levels are appropriately regulated, the way in which they are distributed across the chromosomes does not impact metabolic performance.
2. No chromosome is an island. Distributing functionally related genes across many chromosomes establishes an interdependency on chromosome composition. This could serve to maintain genome integrity over evolutionary timescales because the loss or gain of a chromosome is then catastrophic (i.e. severely compromises the fitness of the individual). Note that the glucose oxidation pathway alone ''links'' 14 of 24 chromosomes.
3. If two genes need to be coexpressed simultaneously, they do not have to reside next to each other. The only necessary constraint is that they need to be located downstream from promoter domains that respond to the same regulatory controls. The implication here is a very important point because it suggests that although gene location may not show distributional patterns, it is likely that promoter and regulatory sequences do.
4. Genomes are incredibly successful at adapting to the necessity of generating multiple expression profiles (development, tissue-specific, stress-response, environmental adaptation). This genotype to phenotype expression requires a great potential for recombinatorial diversity. Keeping pathway components separated allows for a large biological potential in expression diversity because sequential pathway reactions are not ''hard-wired'' (directly linked) to one another.

Of these four points, the first and second fall within the larger realm of

organismal evolution and are beyond the scope of this article. The third and fourth points represent the current frontiers of exploration in understanding eukaryotic genome organization.

The physical colocation of genes is not a necessary requirement of coordinated expression. In fact, it would appear to be the exception rather than the rule in terms of how genes are distributed across chromosomes. Given that genes are unequally distributed across chromosomes and that local transcriptional activities vary as a function of local gene densities (Sect. 4.2), a first hypothesis for a mechanism to establish parallel transcriptional controls would be for genes requiring similar expression patterns to be located in similar genetic neighborhoods (i.e. similar gene densities and transcriptional activities). To assess this potential for expression linkage, we have examined the local domains of the glycolytic enzymes (first nine enzymes in Table 1) looking at the number of sequence tags within a ±1 cR window surrounding a locus and the expression levels of those tagged transcripts. These cR measurements have been assessed using the GB-94 panel (GeneMap'99) where, 1 cR corresponds to ~280 kb of DNA. In Fig. 13, the number of SAGE tags are used as an index of the transcriptional activity surrounding each glycolytic gene locus, with the domain total equivalent to the total amount of transcription in the 2 cR window and the gene total being the

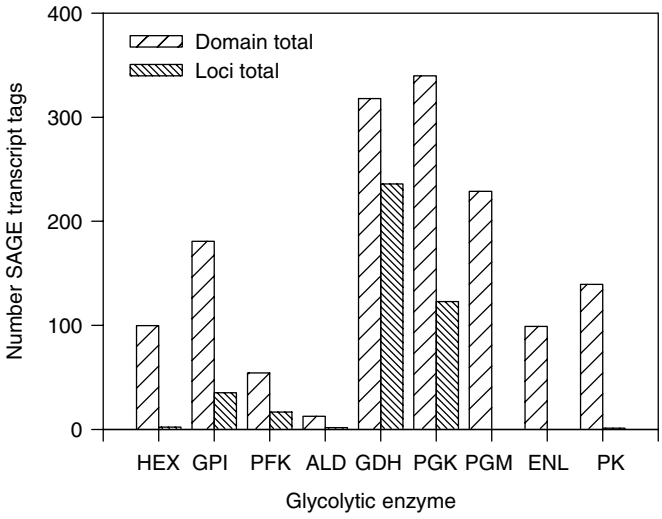

Fig. 13 Transcriptional activity in the loci domains for the glycolytic enzymes presented in Table 1. SAGE transcript tags for a ±1 cR region (GeneMap'99-GB4) around each gene loci were enumerated using the Human Transcriptome Map resources for average expression levels across 12 tissue types total. The histogram bars plot: (1) the total transcriptional activity over a 2 cR region (number of SAGE marker hits), and (2) the transcriptional activity of each gene locus (see chromosomal location data in Table 1). Despite the coordinated, biochemical activity of these genes for glycolysis, there appears to be no direct common transcriptional features regarding the chromosomal domains where these genes reside.

transcriptional activity of the individual locus. Here, there is no apparent relationship between the transcriptional domains of sequential glycolytic gene loci. The only two genes that come close to having similar domains are GDH and PGK, each with high domain totals and high individual levels of expression.

Much significance has been placed on the domain organization of genes into regions of differential expression activity; however, this appears to be a simple tautological observation, that is, that areas dense with genes show higher expression levels because they have more genes. This was one of the fundamental hypotheses of Bernardi in describing the phenomenological nature of isochore organization, which we have seen substantiated. Thus, future efforts to correlate gene expression levels across wide domains do not appear to be a fruitful avenue of research. The genetic complexity of a 500-Mb window is just too great to summarize with a single, average metric. Although it is a conceptually enticing approach in terms of design simplification, measurements of SAGE hits, %GC, GC_3 frequency, CpG islands, isochore boundaries, and so on, cannot describe the molecular mechanism underlying the dynamic expression linkages that are evident.

Intriguing new insights into the distribution of cis-regulatory elements across chromosomes is beginning to show distinctive spatial patterns that could potentially lead to an understanding of why genes are distributed the way they are. Characterizing sequence structures over small windows (~100 bp) has revealed a remarkable degree of consistent patterns in upstream regulatory sequences and exon/intron splicing boundaries. These patterns indicate a consistent spatial organization in regulatory domains that is independent of chromosomal location. Two big challenges to overcome in clearly identifying such cis-regulatory mechanisms is the difficulty of finding statistically significant sequence motifs in such short motifs and the development of quantitative models of regulatory interactions that can explain sequence structural organization.

4.5 Importance of Expression Controls

Another new frontier in assessing genomic organization is describing the mechanistic basis for the recombinatorial diversity of gene expression activities. In eukaryotes, gene promoter domains are rarely triggered by single activators or repressors. Instead, multiple interactions between several target sites within a promoter domain, and between several activating or repressing protein factors at each of those sites, results in the regulation of transcription rates. Consequently, the expression of a gene within a cell is more accurately described as a probabilistic function, rather than a deterministic one, that is, all cells within a tissue do not have the same expression profile at any instant in time. There is the potential for significant variation in expression levels, which is one of the key features of the successful organization of a genome in perpetuating a biological system.

We are now just beginning to see data quantifying levels of variance in gene expression rates. In a comprehensive study of expression patterns in yeast cells, only 7% of the statistically significant changes in gene expression levels following experimental stimuli were actually functional, that is, directly related to altering the cellular physiology of the yeast to accommodate the stimuli. The

remaining 93% of ''significant'' gene expression activity was essentially ''random.'' In vertebrates, the significance of accounting for individual variance in gene expression levels has been documented in fish, and this approach is now being applied to screening human microarray expression data for disease detection by establishing a critical threshold of detection relative to differences in expression levels between different individuals.

Thirty years ago, scientists were amazed at how similar in composition the chromosomes of chimpanzees and humans appeared to be. This lead to the hypothesis that one of the primary forces in species evolution was not mutations in coding gene domains, but subtle alterations in the timing and expression levels of those genes. When it became clear that humans essentially had only three times the number of genes as in the fly *Drosophila*, we realized that coding gene domains were not the only evolutionary game in play. The large difference in biological system organization between humans and flies is likely impacted by the timing, magnitude, and coordination of gene expression events just as significantly as gene exon domains. Overall, the probabilistic (not deterministic) nature of gene expression controls will likely become one of the primary mechanisms determining how and where genes are distributed within the human genome.

Keywords

Internal Ribosome Entry Site (IRES)
A region of RNA containing sequences and secondary structures that facilitate the cap-independent recruitment of ribosomes and initiation factors for translation of a downstream gene.

Noncoding Region (NCR)
A sequence of RNA that is not translated into protein.

RNA-dependent RNA Polymerase
An enzyme capable of elongating ribonucleic acid chains from an RNA template.

Proteinase
An enzyme that recognizes and cleaves specific peptide sequences within a protein or a subset of proteins.

Cap-independent Translation
A mechanism of translation that does not rely on the recognition of a 7-methyl-guanosine (m^7G) cap structure linked to the 5′ end of an mRNA by translation initiation factors.

Polyprotein
A large polypeptide containing the amino acid sequences of more than one mature gene product.

Picornaviruses are the agents responsible for numerous diseases of varying severities that affect the population of the world whose susceptible hosts include humans and other vertebrates. These viruses are presently classified into seven major genera and are responsible for diseases like paralytic poliomyelitis (poliovirus), myocarditis (coxsackievirus), the common cold (rhinovirus), hepatitis (hepatitis A virus), and foot-and-mouth disease (foot-and-mouth disease virus). Despite the ability of these viruses to cause a wide array of maladies, they all share common features among their replication and gene expression strategies, often allowing insights from studies on one virus to be applied to another. With the advent of powerful molecular biology techniques, picornaviruses have provided a wealth of information surrounding protein–protein and protein–RNA interactions that are critical for the process of viral replication and subversion of the host cell. Importantly, this has also furthered our understanding of eukaryotic gene expression and the regulation of other host cell processes.

1 Introduction

1.1 Taxonomy of Picornaviruses

The family *Picornaviridae* (*pico* means ''small,'' i.e. small RNA virus) consists of seven major genera: enteroviruses, rhinoviruses, cardioviruses, aphthoviruses, hepatoviruses, parechoviruses, and teschoviruses. Parechoviruses and teschoviruses have been described only recently, as have two less-populated genera (kobuviruses and erboviruses). Table 1 shows a summary of these genera and representative virus(es) from each. These classifications are based primarily on virion properties (pH stability, sedimentation coefficients, buoyant densities), sequence homology, and differences in genome organization (discussed later in this article).

1.2 Disease Outcomes

Picornaviruses are responsible for significant diseases in a number of different hosts. The prototypic picornavirus, poliovirus (PV), causes poliomyelitis, a once feared disease that can cause a crippling form of paralysis. Interestingly, poliomyelitis is one of the earliest viral diseases ever to be documented, its clinical manifestations depicted on an Egyptian stele dating back to ~1400 B.C. Though largely considered a historic epidemic, there are regions of the world (primarily portions of Africa, India, and China) not yet certified ''polio free'' that have experienced outbreaks of paralytic poliovirus infection from unknown sources as recently as the year 2000. Much attention has also been focused on foot-and-mouth disease virus (FMDV), primarily due to a major outbreak in the United Kingdom and other areas of Europe in 2001 that resulted in the loss of substantial numbers of sheep and cattle, carrying with it dire economic consequences. Human rhinovirus (HRV) is responsible for causing the common cold, the single most prevalent reason for loss of workplace hours due to employee illness. Infection with coxsackievirus (CV) A16 can result in ''hand, foot-and-mouth

Tab. 1 Genera of picornaviridae and representative species.

Genus	*Species*
Enteroviruses	Poliovirus (PV)
	Coxsackievirus (CV)
	Porcine enterovirus (PEV)
Rhinoviruses	Human rhinovirus (HRV)
	Bovine rhinovirus (BRV)
Cardioviruses	Mengovirus
	Encephalomyocarditis virus (EMCV)
	Theiler's murine encephalomyocarditis virus (TMEV)
Aphthoviruses	Foot-and-mouth disease virus (FMDV)
Hepatoviruses	Hepatitis A virus (HAV)
Parechoviruses	Human parechovirus (HPev)
Teschoviruses	Porcine teschnovirus (PTV)
Kobuviruses	Aichi virus (AiV)
Erboviruses	Equine rhinitis B virus (ERBV)

disease'' primarily in young children, whereas other strains of coxsackievirus are responsible for more rare symptoms including myocarditis, ocular conjunctivitis, and even paralysis. Parechoviruses (originally called *echo*viruses, for *e*nteric *c*ytopathic *h*uman *o*rphan viruses) are known to cause chronic meningoencephalitis, colds, neonatal carditis, and encephalitis. The cardioviruses are primarily mouse pathogens known to cause encephalomyelitis and demyelinating disorders, although there are rare instances of human cardioviral infections. And finally, hepatitis A virus (HAV), a hepatovirus, is a leading cause of liver disease that varies from isolated cases to widespread epidemics.

1.3 Genome Organization

Schematic representations of the genomes of several picornaviruses are depicted in Fig. 1. A typical picornavirus genomic RNA is ~7.0 kb to ~8.5 kb in length, single-stranded, positive-sense, and contains a 3′ poly(A) tract. Instead of a 7-methyl-guanosine cap normally found linked to the 5′ end of cellular mRNAs, picornavirus genomes possess a small viral protein, termed *VPg* (the 3B-gene product), covalently attached to their 5′ ends. VPg is uridylylated by the viral RNA polymerase to produce VPg-pU-pU, which acts as a protein primer for the initiation of viral RNA synthesis (discussed in Sect. 4). The genome of a typical picornavirus contains a large polyprotein coding region flanked by 5′ and 3′ noncoding regions (NCRs), which harbor several RNA sequence and structure elements necessary for RNA replication and translation. The 5′ noncoding region contains an IRES or internal ribosome entry site (discussed in Sect. 3), which allows the virus to initiate translation of its viral polyprotein via a cap-independent mechanism. Picornaviruses contain coding regions within their genomes that consist of a single open reading frame used to translate a large viral polyprotein of approximately 250 kDa, which is processed into both precursor and mature cleavage products by different viral-encoded proteinases. All picornaviruses (except for

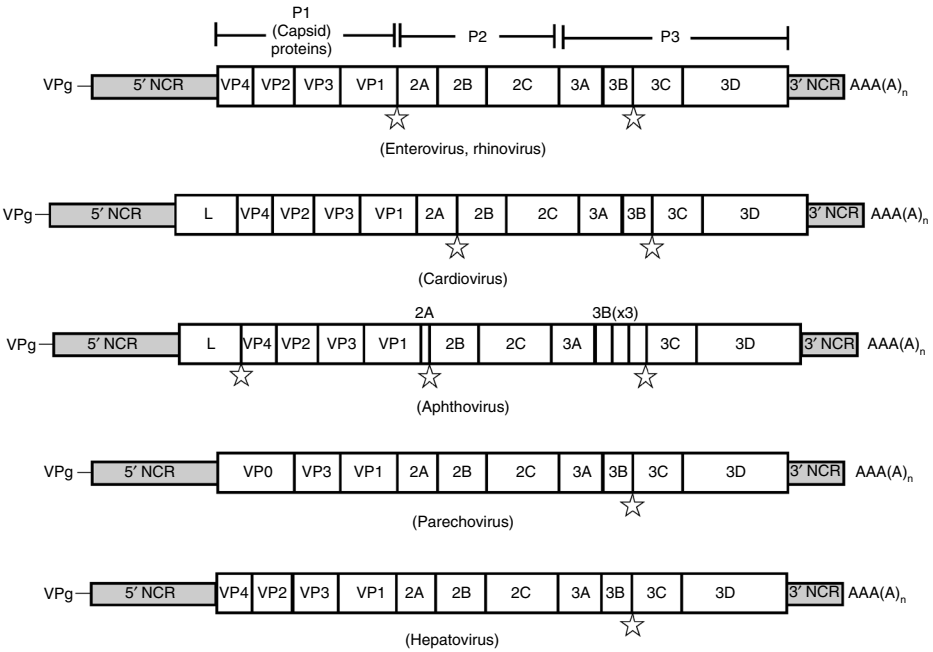

Fig. 1 Schematic of genomes from major genera of *Picornaviridae*. Shown are the genome organizations for entero-/rhinoviruses, cardioviruses, aphthoviruses, parechoviruses, and hepatoviruses. Above the top schematic are the regions of the polyprotein designated P1 (capsid proteins) and P2/P3 (nonstructural proteins). Covalently linked to the 5′ end of each genome is the small viral protein VPg (the 3B gene product) and shown in gray are the 5′ and 3′ noncoding regions, which contain extensive secondary structures (not depicted in the figure). The star(s) shown below each schematic indicate sites of primary cleavage within the viral polyprotein (occurring in cis) that are mediated by viral-encoded activities.

parechoviruses; see Fig. 1) generate four capsid proteins (VP1, VP2, VP3, and VP4), between one and three active proteinases, and six to eight replication proteins. The exact role(s) of the 3′ NCR as it relates to picornavirus replication is not completely understood, but it may contain determinants necessary for optimal RNA replication efficiency in various target tissue types. The 3′ poly(A) tract, absolutely required for viral infectivity, is thought to impart stability to the genomic RNA and is a likely site for replicase assembly involving both viral and host factors. It has recently been proposed that there is molecular ''cross-talk'' between the 3′ NCR, 3′ poly(A) tract, and 5′ NCR involving factors of viral and host origin that mediate RNA replication initiation (discussed in Sect. 4).

2
Virion Properties, Host Cell Binding, Entry, and Uncoating

2.1
Features of the Picornavirus Virion

The typical picornavirus virion is a nonenveloped, icosahedral structure derived from the assembly of 60 copies each of the capsid proteins VP1, VP2, VP3, and VP4.

Although the sequences of VP1, VP2, and VP3 can vary greatly from one picornavirus to another, these proteins always form an eight-stranded β-barrel structure that resembles a ''jelly roll.'' Each virion contains a single copy of the RNA genome, and is void of any other viral proteins except the genome-linked protein VPg. Most picornavirus particles are resistant to harsh environmental conditions and cannot be inactivated with nonionic detergents (due to the absence of an envelope). Some are resistant to low pH. Such stability under low pH conditions allows enteroviruses, for example, to be resistant to degradation along the route of infection within the gastrointestinal tract.

2.2 Receptors and Virus Adsorption to the Host Cell

Picornaviruses utilize different molecules on the surfaces of target cells for adsorption and subsequent entry (see Table 2). These receptors include proteins, glycolipids, and carbohydrates, and are normally found only on a subset of tissues within certain organisms, resulting in stringent tissue specificity and host range. A majority of the receptors recognized by picornaviruses are members of the immunoglobulin-like superfamily. Three-dimensional studies of several picornaviruses have revealed the presence of a ''canyon'' that forms around the vertex of the fivefold axis of the virion particle and involves amino acids that are highly conserved between different viruses. For some rhinoviruses and enteroviruses, extensive structural studies of virus–receptor interactions have shown the canyon to be the site for binding to the immunoglobulin-like superfamily receptor molecule. This unique property differs from that of other picornaviruses, and viruses in general, that normally rely on molecules extending from the surface of the virion to participate in these interactions. The canyon morphology found in enteroviruses and rhinoviruses has been proposed to be immune-evasive by reducing the ability of soluble antibodies to recognize this conserved region of the capsid. Recently, a ''pocket factor'' (likely a fatty acid derived from the host) has been visualized in the canyon of rhinoviruses and enteroviruses,

Tab. 2 Cell surface receptors and coreceptors used by some picornaviruses.

Virus	*Receptor*
Poliovirus	Poliovirus receptor (PVR or CD 155)
Human rhinovirus	Intracellular adhesion molecule-1 (ICAM-1)
	Low density lipoprotein receptor (LDL-R)
Encephalomyocarditis virus	Vascular cell adhesion molecule-1 (VCAM-1)
	Sialic acid
Foot-and-mouth disease virus	Vitronectin receptor ($\alpha_v\beta_3$)
	Heparan sulfate
Coxsackievirus	Decay accelerating factor (CD155)
	ICAM-1
	Vitronectin receptor ($\alpha_v\beta_3$)
	Coxsackievirus-adenovirus receptor (CAR)
Parechovirus	Very late antigen-2 (VLA-2; $\alpha_2\beta_1$ integrin)
Hepatitis A virus	Hepatitis A virus cellular receptor-1 (HAVcr-1)

and it has been proposed that this factor somehow stabilizes the virus particle until it is replaced with the appropriate host receptor. Some antiviral compounds stably bind these pocket regions of the capsid, thereby preventing binding to the host cell. In contrast, it has recently been shown that viruses that do not bind immunoglobulin-like superfamily receptors utilize regions of their capsids not within, but just adjacent to this canyon, often involving loop structures on the surface of the virion.

2.3 Virus Uncoating

Independent of the cell surface molecule used, binding to the viral receptor triggers events that cause entry of the virus into the host cell and the subsequent uncoating of the virion to release the RNA genome into the cytoplasm. In many cases, the receptor need not be membrane-associated for this phenomenon to occur. For many picornaviruses, it has been shown that receptor-binding results in the loss of VP4 protein and the extrusion of VP1 to the virion surface. This ''metastable'' form of the virion particle may undergo further conformational changes that allow it to insert its RNA genome directly into the cytoplasm through the formation of a pore in the cellular membrane. Interestingly, studies have shown that adsorbed virus eluted from the cellular receptor after undergoing these conformation changes is no longer infectious.

Other picornaviruses, like rhinoviruses and foot-and-mouth disease virus, are known to enter the cell by receptor-mediated endocytosis. An acidification within the endosomal vesicle results in the disassembly of capsid proteins and release of the RNA into the cytoplasm. It is not clear if the uncoating of enterovirus particles (like poliovirus) is actually pH-dependent, since many enteroviruses demonstrate stability even at low pH.

3 Synthesis and Processing of Viral Polyprotein

3.1 Internal Ribosome Entry

Once inside the host cell, the input RNA genome is utilized as a template for the synthesis of structural (capsid) and nonstructural viral proteins. As previously mentioned, picornaviruses employ a cap-independent mechanism of translation initiation, utilizing several secondary structures and sequence elements contained with their 5′ NCRs to mediate a process known as *internal ribosome entry*. The first IRESs were described for poliovirus and encephalomyocarditis virus (EMCV, a cardiovirus) in 1988. Subsequently, it was shown that circular RNAs containing the EMCV 5′ NCR were capable of translation, confirming the fact that internal ribosome entry is an end-independent mechanism. Deletion analyses of several picornavirus IRES elements have revealed the presence of minimal ''core'' sequences necessary for initiation of translation with additional sequences and structures required for optimal translation activity.

The translation of capped cellular messenger RNAs is shut down early in a picornavirus infection (reviewed in Sect. 4), and translation factors that normally mediate host translation are utilized almost exclusively for the synthesis of viral proteins. The 5′ NCRs of all picornaviruses contain multiple AUG codons that are not utilized as authentic start sites for translation initiation, and the high degree of

secondary (and likely tertiary) structures found within this region of the genome prevents the ribosome from scanning to find the appropriate initiator codon. Therefore, picornaviruses use the combination of host-initiation factors and IRES elements to facilitate recruitment of the 43S ternary complex downstream of the nonauthentic AUG codons. Once there, ribosome scanning is thought to occur as it does in cap-dependent translation.

Primarily, on the basis of structural differences, two major types of IRES elements have been described for picornaviruses. For example, entero- and rhinoviruses possess type I IRES elements, whereas aphtho- and cardioviruses have a type II IRES. Initially, IRES structure was based on predictions by computer-generated folding and structure probing. More recently, visualization of IRES tertiary structure by transmission electron microscopy has been done with some picornaviruses (i.e. human rhinovirus, foot-and-mouth disease virus, hepatitis A virus) and has confirmed these initial predictions. Interestingly, IRES elements are not unique to picornaviruses, as other viruses (e.g. hepatitis C virus (a flavivirus), human herpesvirus (a DNA virus), and several retroviruses) utilize these elements for translation initiation. Furthermore, numerous eukaryotic mRNAs also possess IRESs and are capable of translation even during the early stages of a picornavirus infection (e.g. c-myc, fibroblast growth factor, Bip).

3.2 Host Proteins Involved in IRES-mediated Translation

All picornavirus internal ribosome entry sites investigated to date utilize several canonical host translation factors that recognize specific sequences and structures within the 5′ NCR, as well as other RNA binding factors of cellular origin. Evidence for this initially came from the fact that the picornavirus genome is translated immediately upon entering the cytoplasm of the host cell in the complete absence of any proteins of viral origin. Furthermore, several picornaviruses display cell-type and tissue-specific differences in IRES-mediated translation efficiencies, suggesting that these host factors play a critical role in virus tropism and tissue specificity within the host.

All picornavirus IRES elements utilize eukaryotic initiation factors to mediate translation. These include protein components of the eIF2 and eIF3 complexes, as well as some eIF4F (cap-binding complex) factors like eIF4A and 4B. Interestingly, several picornaviruses utilize a cleavage product of eIF4G generated from proteolysis mediated by the 2A or L proteinase (see Sect. 3.4), which simultaneously shuts down cap-dependent host protein synthesis. Consisting of the carboxy-terminal two-thirds of the protein, the cleavage product of eIF4G contains both the binding site for eIF3 and eIF4A, and can mediate IRES-driven translation initiation.

In addition to canonical eukaryotic translation factors, picornaviruses utilize several other host proteins for translation of their viral RNAs. Two proteins, La (lupus autoantigen) and PTB (polypyrimidine-tract binding protein), were the first described as having such a role. PTB has been shown to bind to multiple sites within the IRES of polio-, encephalomyocarditis- and foot-and-mouth disease virus, and different homologs of this protein have been shown to contribute to the ability of certain viruses (i.e. Theiler's murine encephalomyocarditis virus or TMEV) to replicate in particular cell types.

Furthermore, La is another instance of a host protein that retains activity in viral translation despite being cleaved by a viral proteinase, as is the case during a poliovirus infection. It has been proposed that proteins like La and PTB somehow stimulate the recruitment and assembly of translation initiation complexes by interacting with both the viral RNA and with various canonical host translation factors. In addition, other host proteins like PCBP (poly(rC)-binding protein) and unr (upstream of N-ras) have been shown to interact and stimulate translation of several picornavirus IRES elements.

3.3 Overview of Viral Protein Functions

Once translation begins, the viral polyprotein is synthesized. It is then cleaved by viral-encoded proteinases into several structural (capsid proteins encoded in the P1 region of the genome) and nonstructural (P2 and P3) proteins. Additionally, aphthoviruses and cardioviruses contain a leader protein (L) at the very amino-terminus of the polyprotein. This protein functions as a proteinase during aphthovirus infections; however, it does not function as a proteinase during cardioviral replication and its precise function is not yet known. The nonstructural proteins carry out several functions in the infected cell necessary to dramatically alter the intracellular environment to make it suitable for subsequent rounds of translation and RNA replication. This involves the use of not only mature viral proteins but several precursors to these proteins as well. Major functions of these proteins include a rearrangement of host membranes (2C and/or 2BC), changing overall membrane permeability (2B), altering nuclear trafficking patterns and Class I Major Histocompatibility Complex expression (3A), and the shutoff of host translation (i.e. L for aphthoviruses, 2A for enteroviruses, and rhinoviruses) and transcription (3C/3CD). Other P3-region proteins are responsible for the priming of RNA synthesis (VPg, the viral protein 3B), RNA elongation (3D), association of replication complexes with membranous vesicles (3AB), and the assembly of ribonucleoprotein complexes required for RNA synthesis initiation (i.e. 2BC, 3CD, and 3AB). The specific functions of several picornavirus nonstructural proteins will be described in greater detail in Sect. 4 of this article.

3.4 Viral-encoded Proteinases

All picornavirus genomes encode a single, large polyprotein, which is never actually observed during an infection. First suggested more than 35 years ago by Donald Summers and Jacob Maizel at the Albert Einstein College of Medicine, it is now known that viral proteinases are responsible for the co- and posttranslational processing of the viral polyprotein into its component structural and nonstructural proteins. This processing cascade is initiated by a primary cleavage event (occurring in cis i.e. monomolecular) that involves recognition of specific junction(s) within the polyprotein. The remainder of the cleavage events could also occur in cis but likely occur in trans (i.e. bimolecular). Since picornavirus proteinases contain sequences and structural features found in other well-known proteases, their study in the context of substrate recognition has furthered our knowledge regarding enzyme–substrate interactions in general. For picornaviruses, three major viral proteinase types have been

described: the L, 2A, and 3C-containing proteinases.

The L proteinase, located at the very amino-terminus of the aphthovirus polyprotein, is a thiol protease that adopts a fold, which resembles that of the enzyme papain. This protein cleaves itself from the viral polyprotein at its own carboxy-terminus (the L-P1 junction). The major function of the aphthovirus L proteinase is the cleavage of the eIF-4G component of eIF-4F, a host cell protein complex critical for cap-dependent translation initiation. This cleavage event mediates, in part, the host cell shutoff during an aphthovirus infection (described above).

The 2A proteinase is responsible for the primary cis cleavage event during enterovirus and rhinovirus polyprotein processing. This involves the cleavage of the scissile bond at the amino-terminus of 2A, liberating the P1 (capsid) polyprotein from P2-P3. The 2A protein of enteroviruses and rhinoviruses adopts a fold similar to that of chymotrypsin (a serine protease) but utilizes a cysteine as a nucleophile rather than a serine. Similar to the L proteinase of aphthoviruses, the major function of the 2A proteinase during enterovirus and rhinovirus infections is the cleavage of eIF-4G, which mediates the shutoff of host cell cap-dependent translation. Interestingly, it has also been suggested that the 2A protein of entero- and rhinoviruses plays a direct role in mediating cap-independent translation, and could also play other roles in RNA replication. For poliovirus, it appears that 2A contains sequences that are not required for proteolytic activity but are necessary for efficient RNA replication. The 2A protein of aphthoviruses, cardioviruses, and hepatoviruses is not proteolytically active. In hepatoviruses, 2A is cleaved from the polyprotein by the 3C proteinase, whereas, in the case of aphthoviruses and cardioviruses, the primary cleavage at the carboxy-terminus of 2A occurs by an undefined mechanism that does not rely on the proteolytic activity of any viral proteinase (i.e. 2A, L, or 3C). For these viruses, it is thought that a conserved tetrapeptide motif (NPGP) could be responsible for the autocatalytic release of the 2A carboxy-terminus from the rest of the polyprotein via a breakage of the Gly–Pro bond. If not mediated by the tetrapeptide itself, this cleavage could be carried out by a cellular protease. A more intriguing possibility is the termination of translation just downstream of the conserved glycine residue, thereby preventing formation of the Gly–Pro peptide bond altogether.

The 3C proteinase is responsible for the majority of the cleavage events occurring within the picornavirus polyprotein that are not mediated by the L or 2A proteinases. This highly conserved proteinase adopts a fold similar to that of the serine protease chymotrypsin and is produced by all known picornaviruses. Extensive studies have shown that, for poliovirus, the immediate proteinase precursor (3CD) displays an increased ability to process polyprotein, specifically the capsid (P1) region. Furthermore, the structural and sequence context of the dipeptide, recognized by 3C proteinases (primarily Q-G), is critical for its cleavage activity, a likely reason why all additional Q-G dipeptide sequences present within the viral polyprotein are not recognized by 3C. Studies have also shown that 3C recognizes other substrates of nonviral origin. 3C is responsible for cleaving cellular proteins necessary for host transcription (e.g. TATA binding protein, Oct-1, and transcription factor IIIC), thereby mediating the shutoff of RNA synthesis catalyzed by all three types of cellular RNA polymerase. This presumably requires the ability of

3C to enter the nucleus of the infected cell, and it has been shown that a putative nuclear localization signal (KKKRD), conserved in all picornavirus polymerases, allows the 3CD proteinase precursor to shuttle into the nucleus. Additionally, it has been shown that the poliovirus 3C and/or 3CD proteinase cleaves poly(A) binding protein (PABP) at late times postinfection, which could serve to inhibit cap-dependent translation or destabilize cellular mRNAs.

4
Viral RNA Replication and Packaging

Picornaviruses utilize a relatively small number of viral-encoded gene products to dramatically alter the intracellular environment to allow the specific and rapid amplification of their RNA genomes. This involves extensive virus–host interactions at several intracellular locations and includes the formation of protein–protein and protein–RNA complexes that allow viral replication to occur with limited interference from host defense mechanisms. As outlined below, some of these macromolecular interactions are well-characterized while others are thus far a mystery. This section gives a summary of host cell modifications brought about by a picornavirus infection that are necessary for successful viral replication, followed by summaries of separate viral gene products and their precursors (where applicable) to which distinct replicative functions have been ascribed. It should be noted, however, that there is increasing evidence suggesting that RNA replication complexes assemble with whole precursor (i.e. P2-P3, P2, or P3) forms of these proteins. Proteolysis then occurs subsequent to the assembly of these complexes, generating the immediate precursor and mature polypeptides to carry out the functions described below.

4.1
Modification of the Host Cell Environment

Following the translation and processing of the viral polyprotein by viral-encoded proteinases, an abrupt decrease in the level of cellular cap-dependent translation occurs as the cap-binding complex, eIF-4F, no longer recognizes capped cellular mRNAs due to the proteolytic cleavage of one of its component polypeptides, eIF-4G (see, Sect. 3.4) or other mechanisms involving the sequestration of the cap-binding protein eIF-4E. This occurs within 2 h postinfection and results in the complete hijacking of the eukaryotic translation apparatus that is used exclusively for viral protein synthesis. The process of host cell shutoff was initially thought to involve one or more cellular proteinases that become ''activated'' by the picornavirus proteinase. However, 2A-mediated eIF-4G cleavage can be reconstituted with purified components *in vitro*, demonstrating that this process can occur in the absence of any cellular proteins. As previously mentioned, the products of eIF-4G cleavage actually participate in the process of IRES-mediated viral translation.

A hallmark of a typical picornavirus infection is the rearrangement of host intracellular membranes, mediated primarily by proteins encoded in the P2 region of the picornavirus genome, resulting in the formation of rosette-like structures consisting of endoplasmic reticulum and Golgi-derived membranes. This rearrangement compartmentalizes the intracellular environment, allowing certain

host and viral proteins to associate specifically with the genomic RNA while nonessential factors are excluded. The association of viral RNA with vesicles is maintained by proteins (described below) contained within the P2 and P3 regions of the genome that anchor RNA replication complexes. In addition to their physical arrangement, the protein-trafficking properties of these membranes also change. For example, a poliovirus infection inhibits ER-to-Golgi transport and increases membrane permeability. Interestingly, poliovirus may also utilize these membrane modifications to evade the host immune response by downregulating the transport of Class I Major Histocompatibility Complex molecules to the surface of the cell. While the transport of certain proteins to the plasma membrane is inhibited, others, like viral receptor molecules, are upregulated during an infection. Picornaviruses also modify nuclear-cytoplasmic trafficking within the infected cell by altering the nuclear pore complex, perhaps allowing the virus to utilize one or more host nuclear proteins for RNA replication occurring in the cytoplasm.

Many picornavirus infections also influence cellular signal transduction pathways by changing the phosphorylation patterns of their protein components. It was shown that infection of L929 (mouse fibroblast) cells by EMCV alters the phosphorylation state of one or more proteins in the MAP kinase pathway, activating them for use in IRES-mediated viral translation. It appears that other picornaviruses, including coxsackievirus (an enterovirus), also take advantage of these same pathways to mediate replication processes. Picornaviruses downmodulate several components of the apoptotic pathway (e.g. procaspases) to prevent premature cell death during an infection. Since picornaviruses likely replicate via the generation of a double-stranded RNA intermediate, they have also developed means by which to modulate the IFN α/β expression critical for the cellular antiviral response to dsRNA.

4.2 Viral Protein 2A

As previously described, the 2A protein of picornaviruses plays a major role in the shutoff of host protein synthesis (except for aphtho-, cardio-, and hepatoviruses in which 2A is not a proteinase). The active 2A protein catalyzes the primary cleavage event that liberates the P1 (capsid) region of the polyprotein from the P2-P3 (nonstructural) precursor polypeptide. Interestingly, the 2A protein of poliovirus may also play a role in viral RNA replication, involving carboxy-terminal sequences within the PV 2A protein that are not required for cis- or trans-proteolytic activity.

4.3 Viral Protein 2B

The 2B protein modifies intracellular membrane properties by increasing their permeability, inhibiting cellular exocytosis, and dissociating the Golgi complex to form vesicles upon which RNA replication occurs. It has been proposed that the increase in membrane permeability could be critical at late stages during an infection by facilitating the release of newly formed virions. Though its exact role has not been defined, the 2B protein is critical to the process of viral RNA replication since viruses harboring mutations in this gene have a small plaque phenotype and cannot be complemented in trans.

4.4 Viral Proteins 2C and 2BC

A precise function for the picornavirus 2C protein has not yet been described. However, 2C plays a role in the initiation of viral negative-strand RNA synthesis and contains NTPase motifs that are homologous to those found in DNA helicases. 2C helicase activity has not been observed directly, but its NTPase activity has been demonstrated. This NTPase activity is inhibited by guanidine-HCl, a chaotropic agent that prevents negative-strand RNA synthesis. Furthermore, guanidine-HCl resistant viruses contain mutations in their 2C coding sequences, lending support to the idea that this protein is critical to the process of RNA replication. Additionally, 2C may have a role in RNA encapsidation, as viruses resistant to encapsidation inhibitors (i.e. hydantoin), contain mutations in their 2C coding regions.

The 2C protein contains two known RNA binding motifs, and it is thought that this protein, along with its immediate precursor 2BC, binds sequences in the 3′ NCR of the negative-strand viral RNA to mediate positive-strand RNA synthesis initiation. In addition to functioning as RNA binding proteins, the 2C and 2BC polypeptides are critical for vesicle formation and directly associate with membranes in RNA replication centers. Indeed, the expression of these proteins in HeLa cells (in the absence of a viral infection) leads to the formation of membranous structures identical to those seen in a picornavirus infection. However, subsequent viral infection of the morphologically altered HeLa cells has shown that the preformed vesicles are not utilized by the incoming virus for RNA replication, demonstrating roles for these proteins in linking RNA replication to vesicle formation.

4.5 Viral Protein 3A

Protein 3A is a small, hydrophobic polypeptide that associates with intracellular membranes and is responsible for the inhibition of protein secretion and intracellular membrane transport. Protein 3A has been shown to be directly responsible for inhibiting the presentation of Class I Major Histocompatibility Complex molecules at the surface of the infected cell and has been shown to decrease the cellular secretion of antiviral cytokines such as IL-6 (interleukin-6), IL-8, and IFN-β. Protein 3A may contribute to the ability of picornaviruses to evade host immunity and could act in concert with viral protein 2C and/or 2BC in rearranging membranes into replication vesicles.

4.6 Viral Proteins 3B and 3AB

3B (also known as VPg) is a small, highly charged polypeptide that is covalently linked to the 5′ end of both positive- and negative-strand viral RNA. 3B (VPg) is a substrate for uridylylation (at a tyrosine conserved in all picornaviruses) by the viral RNA-dependent RNA polymerase, 3D. In addition to the presence of VPg covalently coupled to the 5′ end of negative- and positive-strand viral RNAs, the fact that all picornavirus RNAs begin with uridine nucleotides strongly suggests that VPg is the protein primer for RNA synthesis. Details surrounding RNA synthesis initiation and VPg are discussed later in this section.

Viral protein 3AB could act as an immediate precursor to the 3B (VPg) polypeptide

that assembles with other proteins in replication complexes. The 3AB polypeptide may provide a source of VPg localized to membranous replication complexes, since the 3A region of 3AB contains hydrophobic sequences known to mediate insertion of 3AB into vesicles. It has been shown that 3AB interacts with and stimulates the activity of the 3CD proteinase and 3D RNA-dependent RNA polymerase. In this regard, 3AB could recruit the viral polymerase to replication complexes. The 3AB polypeptide can also bind viral RNA sequences within the 3′ NCR of the genomic RNA; and via protein–protein contacts with the 3CD or 3D polypeptide, could localize the polymerase to the site of negative-strand synthesis initiation. The importance of the 3AB precursor protein is underscored by the fact that some picornavirus RNAs possessing optimized 3A/3B cleavage junctions are deficient in viral RNA synthesis but can be complemented with 3AB or 3ABC precursor polypeptides in trans.

4.7 Viral Proteins 3C and 3CD

The viral protein 3C is multifunctional in nature, acting as a chymotrypsin-like proteinase (described in Sect. 3) and binding viral RNA. The three-dimensional structures of the 3C proteinases from poliovirus, hepatitis A virus, and rhinovirus have been solved, and indicate the presence of RNA binding determinants that lie directly opposite the catalytic triad. The best characterized 3C molecule is that of poliovirus, whose immediate precursor (the 3CD polypeptide) is also an active proteinase and RNA binding protein. Although 3CD is also the precursor to the 3D RNA-dependent RNA polymerase, it does not possess measurable elongation activity *in vitro*. The presence of 3D polymerase sequences in the context of 3CD appears to enhance the ability of 3C to bind viral RNA and process polyprotein (specifically the P1 capsid precursor).

The 3CD precursor polypeptide plays central roles in viral RNA replication. 3CD forms a complex with host protein, PCBP and a viral RNA secondary structure (''cloverleaf'') contained within the first ~100 nucleotides of the positive-strand RNA genome. Although the primary RNA binding determinants reside within the 3C portion of the 3CD polypeptide, it has been suggested that secondary, possibly lower affinity, binding determinants exist in the 3D polymerase domain of the molecule. The 3CD/PCBP/RNA cloverleaf complex is absolutely essential for RNA replication, with genetic evidence pointing to a role in negative-strand RNA synthesis. Since 3CD and PCBP participate in protein–protein contacts with PABP, it has been hypothesized that a long-range interaction could occur involving PABP bound to the 3′ poly(A) tract at the 3′ end of the viral RNA with 3CD and PCBP bound to the 5′ cloverleaf. Once assembled, a cis or trans cleavage of the 3CD molecule could occur to yield a 3D polymerase molecule that elongates from the VPg-primed template.

Finally, 3CD likely plays an important role in protein-primed viral RNA synthesis initiation. The process of VPg uridylylation, catalyzed by the 3D polymerase and responsible for generating the VPg-pU-pU RNA synthesis primer, is greatly stimulated (100 to 1000-fold) by the 3CD polypeptide. The mechanism behind this effect is unclear, but could involve direct binding of 3CD to a cis-acting RNA replication element utilized by picornaviruses as a template for this reaction. More details

regarding this process are given later in this section.

4.8 The Viral RNA-dependent RNA Polymerase 3D

The RNA-dependent RNA polymerases from several picornaviruses have been well-characterized. All are primer-dependent, can recognize and elongate from artificial (nonviral) templates, and are Mg^{2+}-dependent and actinomycin-D insensitive. Similar to those of other RNA viruses, the picornavirus RNA polymerase is highly error prone, misincorporating ~1 to 2 nucleotides per template copying event. Although this results in error prone replication, whereby a slight increase in mutation frequency could dramatically decrease viral fitness, it allows picornaviruses to evolve very rapidly. Within a given population of replicating viruses, there exist many subpopulations that have each generated unique sets of coding sequence mutations, many of which allow the virus to successfully evade the host antiviral immune response. Despite having an attenuated growth phenotype, the nonneurotropic Sabin vaccine strains of poliovirus are capable of regaining neurotropism via random nucleotide mutations generated by the RNA polymerase, resulting in rare cases of vaccine-derived poliomyelitis. Some drugs (e.g. ribavirin, a ribonucleoside analog) push this delicate equilibrium toward ''error catastrophe'' by increasing nucleotide misincorporation, producing strong antiviral effects. The development of optimized ribonucleoside analogs could yield antiviral drugs with broad-spectrum efficacies against many RNA viruses.

The three-dimensional structure of the poliovirus 3D polymerase has been solved. It adopts the conformation of a cupped ''right-hand,'' a structural organization that is conserved among virtually all known polymerases. The poliovirus 3D polymerase is a highly cooperative enzyme, and utilizes extensive regions of polymerase–polymerase contacts to mediate polymerase oligomerization. This phenomenon was originally observed in the crystal lattice used to determine its three-dimensional structure, and has since been shown to be important for biological activity. ''Interface I,'' involving contacts between the thumb subdomain of one polymerase molecule and the palm subdomain of an adjacent polymerase, is critical for binding primed nucleic acid template. ''Interface II,'' involving interactions between the top of the thumb of one polymerase molecule and the base of the fingers of an adjacent polymerase, is necessary for the formation of catalytic sites necessary for efficient RNA chain elongation. Although polymerase–polymerase interactions have been observed in other RNA polymerases, the extensive interactions observed in the poliovirus polymerase may be unique.

4.9 VPg Uridylylation: Priming RNA Synthesis

The viral RNA-dependent RNA polymerase is the most highly conserved gene amongst members of the family *Picornaviridae*. Not only does it catalyze RNA chain elongation, it also catalyzes the generation of the protein primer itself. The addition of uridine nucleotides via a phosphodiester linkage at an absolutely conserved tyrosine of VPg (the 3B viral gene product) requires only a few reaction components, and can be recapitulated *in vitro* with synthetic VPg (a small protein of 22 amino acids), recombinant 3D polymerase, and a suitable

template. As noted above, the addition of polymerase precursor polypeptide (3CD) greatly stimulates this process *in vitro*. Early studies carried out with reaction components from poliovirus showed that a poly(A) tract alone can act as a template for the 3D-catalyzed synthesis of VPg-pU-pU, suggesting a common location for both VPg uridylylation and the priming of RNA synthesis initiation. However, nascently synthesized VPg-pU-pU may not be immediately used for RNA synthesis initiation, since free uridylylated VPg exists within the infected cell, possibly representing a pool from which VPg primers are taken when necessary.

The effects of a number of mutations within the picornavirus RNA polymerase have been documented in the literature. Work aimed at determining sequences within the polymerase critical for the process of VPg uridylylation has yielded some interesting correlations with previously described RNA synthesis phenotypes of viruses harboring mutations in these regions. For example, a mutation within the 3D RNA polymerase of the Sabin 1 strain of poliovirus was shown to confer a temperature-sensitive defect in VPg uridylylation, suggesting that its tissue-specific replication phenotype could be due, in part, to reduced polymerase activity.

4.10 Cis-acting Replication Elements

The mechanisms involved in the specific recognition of viral RNA in the presence of a vast excess of cellular messenger RNA involves structures and sequences within the picornavirus genome that interact specifically with host and viral proteins, and possibly with each other. In addition to sequences contained within the 5′ and 3′ noncoding regions of the viral RNA, several picornaviruses have been shown to possess structurally conserved RNA hairpins within their genomes that are essential for viral replication. First discovered in the genomic RNA of human rhinovirus 14 (HRV14), *cre* (*c*is-acting *r*eplication *e*lement) structures have also been described for enteroviruses, cardioviruses, and aphthoviruses. For a cre element to facilitate RNA replication, it must be present in a positive-strand context. Furthermore, its location within the genome is highly variable. In fact, the location of a cre element can be genetically manipulated without significantly disrupting RNA replication. A nonfunctional cre element can be complemented by a wild-type cre contained in a different region of the same RNA (i.e. in cis) or in trans from another viral RNA. For unknown reasons, evolutionary pressures have not resulted in a conservation of cre location, as closely related members of the same genus can possess cre elements in very different regions of their genomes. For example, the HRV2 cre element is located within the 2A proteinase gene, whereas the HRV14 cre lies within the VP1 capsid protein-coding region.

Analysis of cis-acting replication elements from a number of different picornaviruses show that they share a similar overall structure but vary in their primary sequences. A conserved AAACA motif has been found in all cre elements described thus far, suggesting only minimal primary sequence elements are required for cre function. It has been shown that the VPg uridylylation reaction is more efficient in the presence of the cre element rather than the 3′ poly(A) tract. For poliovirus, a strand-specific function for the cre element has been described, suggesting that the major role of the poliovirus

cre element is to mediate VPg uridylylation required for positive – rather than negative – strand RNA synthesis initiation. This suggests that poly(A) template-dependent VPg uridylylation could function primarily in negative-strand RNA synthesis initiation, and implicates the existence of strand-specific ribonucleoprotein complexes that form on the viral RNA for positive- versus negative-strand synthesis initiation.

4.11 A Model for Picornavirus RNA Replication

Figure 2 shows a schematic summary of the major steps thought to be involved in the process of picornavirus RNA replication, based largely on *in vitro* and cell culture data from experiments aimed at elucidating the mechanisms that underlie poliovirus (the prototypic picornavirus) RNA synthesis. The first step in the process of viral RNA replication is the synthesis of a negative-strand RNA utilizing the genomic positive-strand RNA as a template. As previously discussed, this utilizes a VPg-primed mechanism to initiate RNA synthesis, presumably near the terminus of the 3′ poly(A) tract. Several viral and/or host factors are thought to participate in complex formation at the 3′ end of the RNA, and the role of the 3′ NCR immediately upstream of the 3′ poly(A) tract is not exactly known. Whereas the 3′ poly(A) tract is absolutely required for picornavirus infectivity, it has been shown that for human rhinovirus and poliovirus, deleting the entire 3′ NCR (but leaving the poly(A) tract intact) does not completely inhibit viral replication. Although viruses harboring 3′ NCR deletions exhibit reduced RNA synthesis levels, they are capable of near wild-type levels of negative-strand RNA synthesis. This suggests that the poly(A) tract alone is sufficient for this process, and sequences and structures within the 3′ NCR may serve to optimize RNA replication initiation subsequent to synthesis of the negative strand.

The 3D RNA polymerase alone is capable of recognizing poly(A)-primer duplex RNA *in vitro*, but it is likely that the 3D polymerase participates in protein–protein interactions with other host and/or viral proteins necessary for efficient RNA synthesis *in vivo*. For example, it has been shown that the 3AB protein stimulates 3D polymerase activity *in vitro*, and 3AB-3D interactions have been confirmed by genetic analysis. Additionally, it is thought that the 3AB protein interacts with processed 3B (VPg) and the 3CD polypeptide, which could recruit the polymerase precursor(s) and VPg to the site of uridylylation at the 3′ poly(A) tract. The 3AB precursor may also anchor replication complexes associated with the viral RNA mediated by 3A amino acid sequences known to associate with membranous vesicles.

Once the negative-strand RNA is synthesized, this RNA is utilized as a template for multiple initiation events that produce large amounts of positive-strand RNAs. It is likely that a functional negative-strand RNA remains at least partially annealed to the positive strand from which it was generated, but this has not been directly demonstrated. Double-stranded RNA has been shown to be infectious in tissue culture, and a typical picornavirus infection results in a strong PKR-mediated dsRNA response in the infected cell, supporting the existence of a double-strand RNA (termed "RF" or *r*eplicative *f*orm) as a biologically relevant intermediate during genome amplification.

At one or more steps during the process of RNA replication, the viral RNA

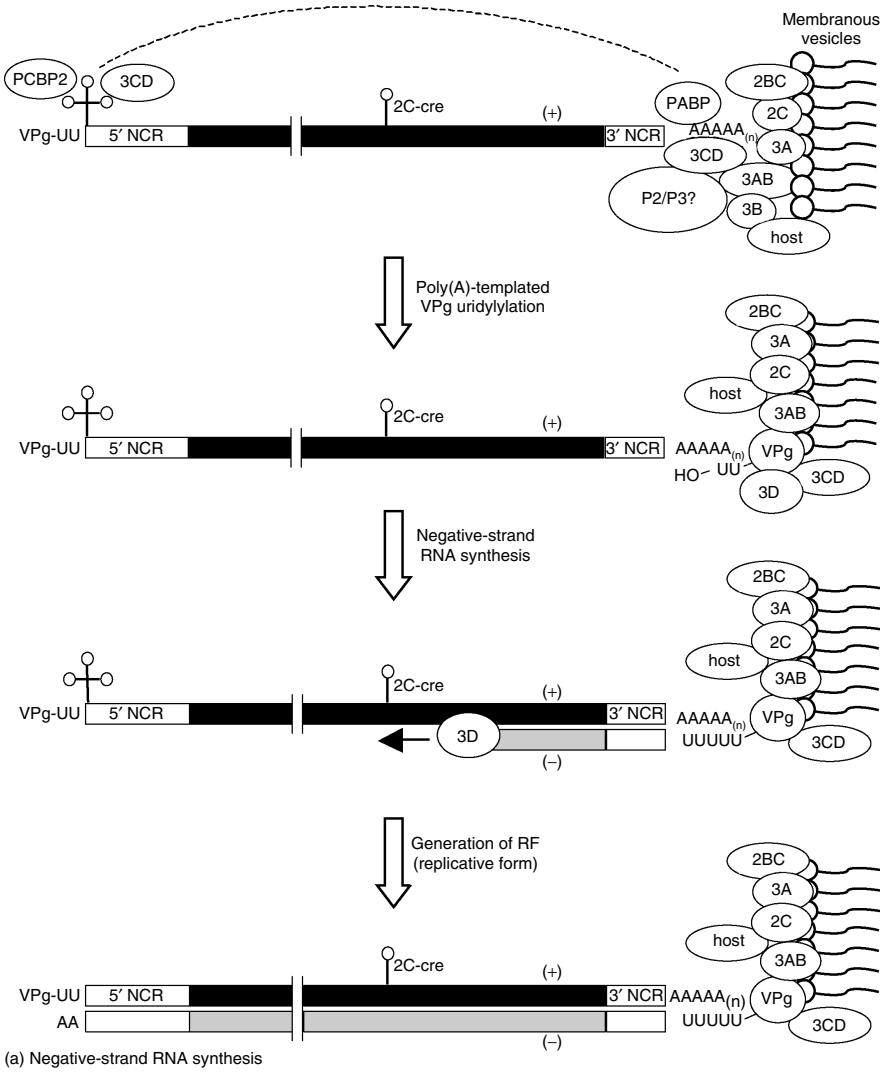

Fig. 2 A proposed mechanism for poliovirus RNA synthesis. (a) Negative-strand RNA synthesis. Precursor polypeptides (P2 and/or P3) or partially processed replication proteins (e.g. 2BC, 2C, 3AB, 3A) along with host factor(s) assemble at the 3′ end of the genomic positive-strand RNA in tight association with membranous vesicles (depicted by open circles and lines representing the polar headgroups of the lipid bilayer). Host protein PCBP2 and viral protein 3CD bind the 5′ RNA cloverleaf and may facilitate long-range contacts (dashed line) with PABP bound to the 3′ poly(A) tract. The 3′ poly(A) tract is utilized as a template for the 3D-catalyzed VPg uridylylation reaction (stimulated by the 3CD precursor polypeptide) to generate the VPg-pU-pU RNA synthesis primer. The 3D RNA polymerase remains associated with the uridylylated VPg or is provided from another source (possibly a 3CD precursor molecule) and catalyzes elongation of the negative-strand RNA, generating the RF (replicative form) dsRNA intermediate.

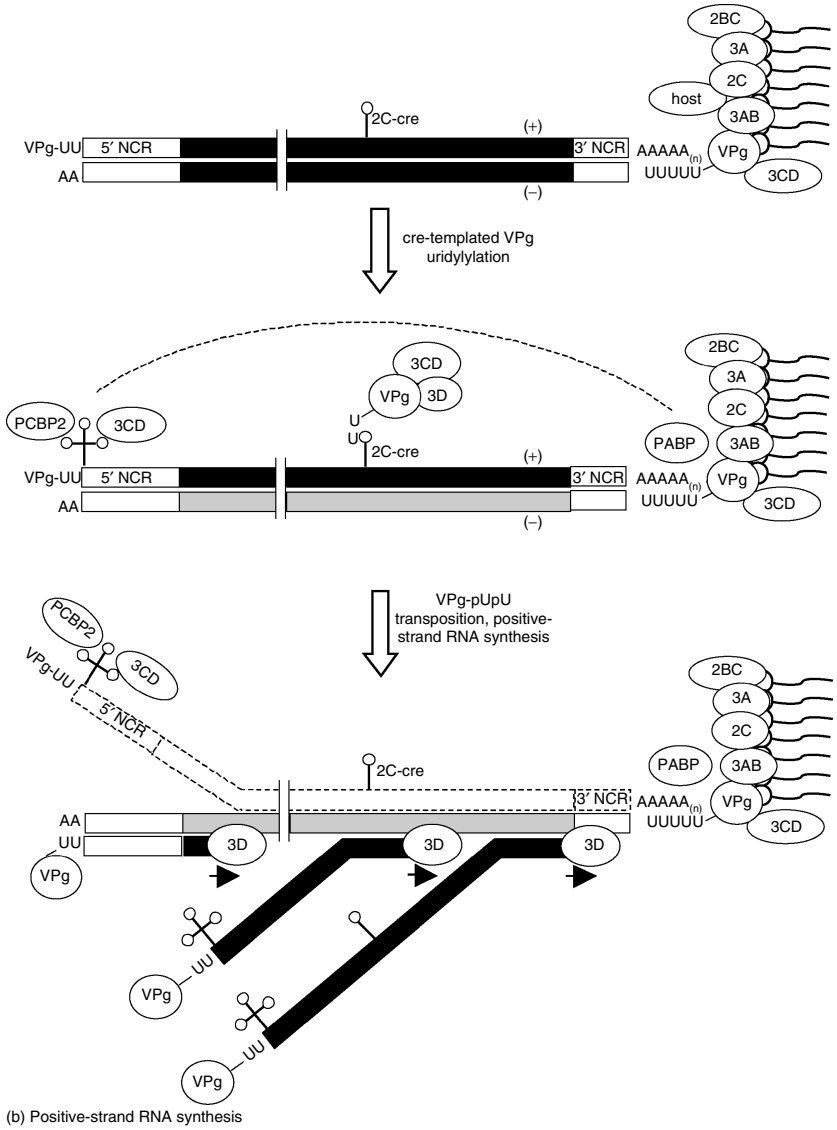

(b) Positive-strand RNA synthesis

Fig. 2 (*Continued*). (b) For positive-strand RNA synthesis, the cis-acting replication element (2C-cre) is utilized as a template for VPg uridylylation (instead of the 3′ poly(A) tract) that may also involve long-range 5′–3′ interactions (dashed line) similar to those described in panel A, facilitating translocation of the resulting VPg-pU-pU primer to the site of positive-strand RNA synthesis initiation. Once annealed to the 3′ end of the negative-strand RNA, the 3D polymerase synthesizes nascent positive-strand RNAs. Multiple RNA synthesis initiation events may occur in succession on the same replicative form dsRNA intermediate, consisting of a positive-strand RNA (indicated by dashed region) that is partially hybridized to a negative-strand RNA. It is not known if the parental positive-strand is displaced during this process by a progeny RNA molecule that remains duplexed with the negative-strand RNA.

could engage in long-range interactions facilitated by proteins bound to the 5′ and 3′ termini of the viral RNA. For poliovirus, PABP has been shown to interact with host protein, PCBP2 and the viral protein 3CD. With PCBP2 and 3CD bound to the cloverleaf element at the 5′ end of the genome, binding to PABP at the 3′ poly(A) tract could allow long-range interactions of the RNA and prepare it for negative- and/or positive-strand synthesis initiation, which could utilize a 3D polymerase liberated via the processing of 3CD within this ribonucleoprotein complex. Such a mechanism for RNA synthesis initiation is thought to occur primarily during negative-strand synthesis initiation, but it may occur for positive-strand synthesis as well. As mentioned, it has been shown that the poliovirus cis-acting replication element (2C-cre) is utilized primarily for the priming of positive-strand RNA synthesis. Given this, it is possible that a dsRNA intermediate (RF) maintains intrastrand contacts to facilitate positive-strand RNA synthesis initiation, bringing the cre element (located in the central portion of the coding sequence) in close proximity to the sites of initiation complex formation and VPg uridylylation.

4.12 RNA Encapsidation and Cell Lysis

The process of viral RNA synthesis results in the production of a vast excess of positive-strand RNA molecules from a single input genomic RNA. As they accumulate, these positive-strand RNAs are utilized as templates for additional rounds of viral translation or RNA synthesis, or they are encapsidated into virion particles. The mechanism by which viral RNA is selected for encapsidation is not clear, but it is likely that one or more signals within the RNA are recognized by viral and/or host factors that trigger encapsidation. On the basis of studies with poliovirus and other picornaviruses (e.g. Aichi virus), these signals may be contained within the IRES element found in the 5′ noncoding region of virion RNA. Furthermore, poliovirus replication carried out in the presence of hydantoin (which inhibits encapsidation) has revealed that the viral protein 2C may play a role in this process, since mutations in the 2C region of the genome confer resistance to this drug.

A schematic of the process of virion assembly is shown in Fig. 3. Once the 3C (or 3CD) proteinase processes the P1 (capsid) precursor polypeptide into VP0, VP3, and VP1, capsid assembly begins with the formation of a ''protomer,'' consisting of one copy of each of these proteins. Five protomers self-associate to form a pentamer, and twelve pentamers then arrange themselves around a newly synthesized RNA, forming the ''provirion'' structure. Alternatively, the pentamers may form an empty capsid structure (the 80S ''procapsid''; see Fig. 3) into which the RNA molecule is threaded. Independent of the assembly pathway, most picornavirus virions undergo a maturation event, which processes VP0 to VP2 and VP4, a cleavage mediated by an undefined proteinase that serves to stabilize the virion particle. This proteinase is not one of the known viral enzymes, and it has been hypothesized that the capsid proteins and/or the genomic RNA itself could carry out this reaction. Once a threshold number of virions are assembled within the infected cell, the cell undergoes lysis to release virus particles that go on to infect neighboring cells. The exact mechanism behind cell lysis is not known.

The release of progeny virions represents the successful culmination of a

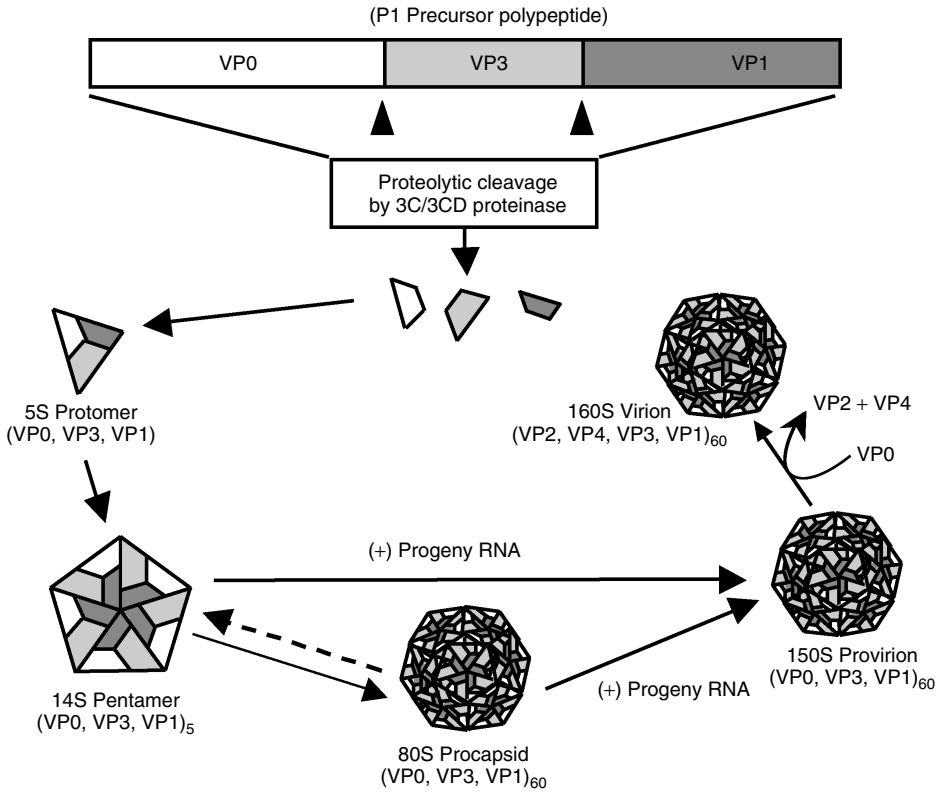

Fig. 3 Assembly of the picornavirus virion. The 3C/3CD proteinase cleaves the P1 capsid precursor to generate VP0, VP3, and VP1. These three proteins assemble into a 5S protomer. Five protomers then assemble into a 14S pentamer. Twelve 14S pentamers may reversibly assemble into the 80S procapsid (indicated by the solid and dashed lines) into which the progeny RNA is threaded, or may themselves assemble around the RNA molecule. In either case, this process results in the formation of the 150S provirion. The provirion undergoes a maturation event (except in parechoviruses), which cleaves VP0 into VP2 and VP4 by an undefined mechanism, forming the mature 160S virion particle.

series of complex protein–protein and protein–RNA interactions that allow a virus with a very limited coding capacity to effectively alter and subsequently utilize machinery within the host for its own translation and replication. Picornaviruses represent some of the most successful of all pathogens known to man, and the study of multilevel virus–host interplay has yielded important insights into not only viral processes but into cellular processes as well. Importantly, picornaviruses that cause very different diseases in their susceptible hosts appear to utilize similar replication strategies that could some day allow for the development of broad-range antiviral treatments that would be effective against several picornavirus infections. This article has attempted to provide a brief overview of some of the interesting aspects of picornavirus replication and gene expression. The reader is encouraged to explore the vast collection of primary research findings that are the basis of this

review, a small portion of which can be found in articles referenced in the bibliography appearing below.

Keywords

BAC (Bacterial Artificial Chromosome)
A vector used in DNA cloning that is capable of carrying DNA inserts measuring 100 to 200 kb.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30547-5

Chromosome-specific Paint Probe
The product of PCR amplification of sorted chromosomes, using random PCR primers. When labeled with fluorochromes coupled to nucleotides in the amplification procedure, the paint probe can be hybridized by fluorescence *in situ* hybridization (FISH) techniques to chromosome preparations on microscope slides. This reveals an even distribution of FISH signals along the chromosomes from which the paint was derived.

Contig
A contiguous series of cloned DNA sequences with overlapping ends.

Cross-species Reciprocal Chromosome Painting
A technique used to identify blocks of chromosome homology shared between species. A chromosome-specific paint probe from species A is hybridized to the chromosomes of species B. Paint probes from species B are hybridized back to the chromosomes of species A. This reveals the chromosomal identity of each homologous region in both species.

Cosmid
A vector used in DNA cloning that is capable of carrying DNA inserts measuring 20 to 40 kb.

FISH (Fluorescence in situ Hybridization)
A method whereby fluorescence–labeled DNA probes are hybridized to their complementary sequences on denatured chromosomes fixed on microscope slides.

Flow Karyotype
Graphic representation of mitotic chromosomes separated by a dual laser flow cytometer according to size and base-pair ratio.

Interchromosomal Rearrangement
A structural chromosome change involving exchange between two or more nonhomologous chromosomes.

Intrachromosomal Rearrangement
A structural change involving inversion or insertion of material within a chromosome.

Plasmid Vector
A vector that can be used for cloning small DNA inserts of 3 to 8 kb.

PCR (Polymerase Chain Reaction)
A method for the primer-directed amplification of DNA sequences.

The ability to sort and collect chromosomes by flow cytometry provides studies on gene mapping and chromosome evolution with a unique source of chromosome-specific DNA. Chromosome-specific gene libraries made from this DNA have yielded genetic markers used in constructing ordered chromosome maps. This was one of the key steps in the project which led to sequencing the human genome. PCR amplification of sorted chromosomal DNA has been used to prepare fluorescence-labeled chromosome-specific probes. When hybridized *in situ* to chromosome preparations, these probes ''paint'' the entire chromosome. The judicious use of different combinations of fluorochromes allows each chromosome pair in the cell to be given a different color. This procedure is helpful in the diagnosis of chromosome rearrangements present in malignant cells or associated with handicapping syndromes. Paint probes from one species can be used to identify homologous chromosome regions in other species. Comparison of the patterns of homology produced by reciprocal cross-species painting adds information on the evolutionary history of a species by distinguishing ancient chromosome rearrangements from those that have occurred more recently. The study of comparative genomics and karyotype evolution owes much to the development of these molecular cytogenetic techniques.

1 Introduction

The fluorescence-activated cell sorter was first used successfully in 1975 to separate chromosomes from fluid suspensions. It was soon found that the method allowed the collection of substantial quantities of chromosomes of one type without cross-contamination with other chromosomes. The chromosome-specific DNA so produced was used to prepare chromosome-specific libraries of DNA in plasmid and other vectors. In the early days of the human genome project, these plasmid libraries were of great importance in cloning chromosome-specific markers, which were used to map individual chromosomes. Linkage of polymorphic markers in family studies allowed the order of markers along the chromosome to be determined, and the detection of linkage between markers and cloned sequences from known genes similarly allowed the assignment of disease and other genes to their location on chromosomes. In the late 1980s, mapping by genetic linkage was supplemented by fluorescence *in situ* hybridization (FISH) mapping in which suitably labeled DNA markers were hybridized *in situ* to their complementary sequences on human chromosomes. With the development of BAC, cosmid, and other vectors for DNA cloning, it became possible to build up series of contiguous sequences of DNA (contigs) along each chromosome on the basis of this preliminary marker map. This approach, coupled with large-scale sequencing of contigs, has been one of the key strategies used in sequencing the human genome. Now that a draft sequence, albeit with gaps, of the entire human chromosome complement has been achieved, chromosome sorting has less application in mapping human genes. However, it still has application

in the building of preliminary maps of unmapped species.

Chromosome-specific DNA prepared from sorted chromosomes may also be used to prepare chromosome-specific probes using the polymerase chain reaction (PCR) with random DNA primers to amplify and label the probes with fluorescent dyes. The resulting labeled DNA is hybridized by FISH to air-dried metaphases on microscope slides in such a way that the respective chromosomes are ''painted'' with fluorescence along the entire length of the chromosome. The technology has advanced to the extent that each chromosome can be recognized by painting with different combinations of fluorochromes (multicolor FISH) in one hybridization experiment. The main application of M-FISH is in the diagnosis of interchromosomal aberrations that cause physical and mental childhood handicap and in the cytogenetic analysis of cancer (see chapter on FISH).

Chromosome painting has played an important part in characterizing regions of genetic homology between chromosomes of different species. The first studies in the early 1990s used chromosome-specific plasmid libraries, but more recent work uses chromosome-specific painting probes amplified from sorted chromosomes. The first comparisons were between humans and other primates. It was confirmed that the karyotype of humans differed from that of the great apes by a tandem fusion of two chromosomes, which formed human chromosome 2 and which occurred after the divergence of the human lineage from the common ancestor with the chimpanzee. Numerous inversions have also occurred during the evolution of the great apes, but the only other interchromosomal rearrangement found was a reciprocal chromosome translocation between human chromosome equivalents 5 and 17 in the divergence of the gorilla. Interchromosomal rearrangements between human and other species have been observed since, some involving whole chromosome arms and some involving smaller segments. The remarkable feature has been the high level of conservation between genomes. The range in the number of conserved (syntenic) autosomal blocks between human and the mammalian species studied to date varies from 23 to 200, the majority in the order of 40 to 50 and the highest in the house mouse. Some rearrangements are more ancient than others and so are shared by a wider range of species. The pattern of rearrangements in a species reflects the history of the genome evolution of that species, and the comparison of patterns between species provides information about their relationship and their place on the evolutionary tree.

2 Fluorescence-activated Chromosome Sorting (FACS)

Chromosomes are sorted using a dual laser flow cytometer equipped with two 5 W argon ion lasers. One laser is tuned to emit 300 mW of light in the UV (351–364 nm) to excite Hoechst fluorescence, and the second laser is tuned to emit 300 mW at 458 nm to excite chromomycin A3 fluorescence.

Chromosome preparations are made by standard methods from short-term blood cultures, lymphoblastoid cell lines, and a variety of tissue culture cells including fibroblasts from biopsy material. Colcemid (0.1 $\mu g\ mL^{-1}$) is added to the actively dividing cell culture to arrest cells in metaphase over several hours. The mitotic cells are collected and

resuspended in 75 mM KCl for 15 min and are transferred to a buffer containing polyamines and Triton X-100. Chromosomes are released into suspension by rapid vortexing for 10 s and are stained with chromomycin A3 (final concentration 40 μg mL^{-1}) and Hoechst 33258 (final concentration 2 μg mL^{-1}) followed by 2 h of incubation at 4 °C. Fifteen minutes prior to flow sorting, sodium citrate (final concentration 10 mM) and sodium sulfate (final concentration 25 mM) are added to the sample. Excessive disruption of the mitotic cells should be avoided as this leads to chromosome fragmentation indicated by an unacceptable level of debris at the lower end of the flow karyotype (Fig. 1). Cultures that contain a high proportion of cells in the anaphase/telophase may also lead to reduced resolution owing to contamination from the inclusion of anaphase chromosomes.

The chromosomes suspended in polyamine buffer, and surrounded by sheath fluid, flow under pressure through the two laser beams sequentially to permit the fluorescence signal emitted from each chromosome to be collected separately and stored in the computer. After the chromosomes have passed through the two lasers, the fluid stream breaks into a series of droplets, some of which will contain a single chromosome. Sorting is achieved by applying an electrical charge to the droplets

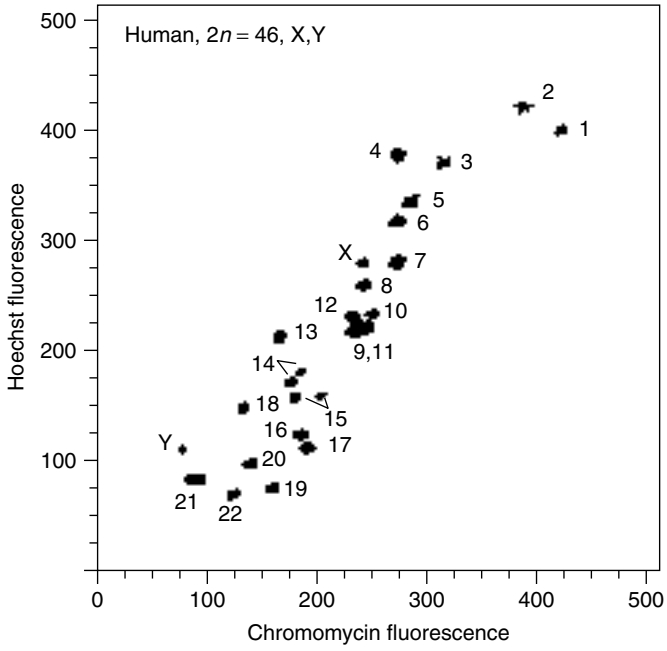

Fig. 1 Flow karyotype constructed from a fluid suspension of metaphase chromosomes from a normal male. The numbered peaks correspond to the numbers used in the classification of the human chromosome complement. Chromosomes are separated on the basis of DNA content and base-pair ratio. Note the separation of homologues of chromosomes 14, 15, and 21 due to heteromorphic blocks of repetitive DNA.

containing the chromosome of interest so that they can be deflected into a container as they pass between two high-voltage plates. Highly pure samples of two types of chromosome can be collected simultaneously. The fluorescence measurements from each chromosome are accumulated in large numbers in the computer and are used to construct a flow karyotype (Fig. 1), which reveals discrete clusters of signals, each cluster representing one or more chromosome types arranged in order of size and base-pair ratio. A–T–rich chromosomes sort above a diagonal line drawn through the middle of the chromosome clusters, while G–C–rich chromosomes sort below the line. The accumulation of signals can be observed on a video monitor and the chromosomes of interest selected for collection by a simple gating procedure. It takes less than 5 min to collect the 300 to 500 chromosomes required for PCR mapping and for the production of chromosome-specific paint probes. Larger samples of 2 to 3 million are required for preparing chromosome-specific DNA libraries, and this requires prolonged sorting.

3 Chromosome Painting

The DNA of 300 to 500 chromosomes sorted by FACS is amplified by degenerate oligonucleotide-primed PCR (DOP-PCR). After a primary round of amplification using the 6-MW primer (5′ CCGACT CGA GNN NNN NAT GTGG 3′) and unlabeled deoxynucleotide triphosphates, the DNA is subjected to a secondary round of amplification, this time incorporating a labeled nucleotide such as biotin-11-dUTP. The biotinylated probe is hybridized to denatured chromosomes in air-dried metaphase preparations using standard FISH methods and is detected using fluorochrome-conjugated streptavidin or anti-biotin antibodies. Many labeling techniques now use fluorescent dyes, such as Cy-dyes, coupled to the nucleotides used in the amplification procedure, and this avoids the need for an additional detection step.

The FISH signals are examined by fluorescence microscopy. An image processing system is helpful in analyzing preparations of low luminosity and in situations in which complex chromosome rearrangements are to be expected. Most digital fluorescence microscopy analysis systems employ a sensitive monochromatic CCD camera and excitation and emission filters appropriate to the fluorescence dye used as a label. When several paint probes, labeled with different combinations of dyes, are used, the gray-scale image of the fluorescence emitted by each fluorochrome is acquired sequentially and merged to produce a composite image in which each paint probe is assigned a separate false color on the computer monitor. Probe sets capable of assigning a different color combination to each pair of chromosomes in the complement are now available for human and mouse, using M-FISH and systems for classification and analysis of karyotypes with interchromosomal rearrangements (Fig. 2). The stored images acquired by these computerized systems are available for color adjustment, image enhancement, image reversal, and a number of other procedures, which assist in chromosome measurement and analysis. Spatial filters and contrast adjustment are particularly useful in enhancing the weak chromosome banding patterns obtained by DAPI counterstaining. Instead of the analysis of images of each individual

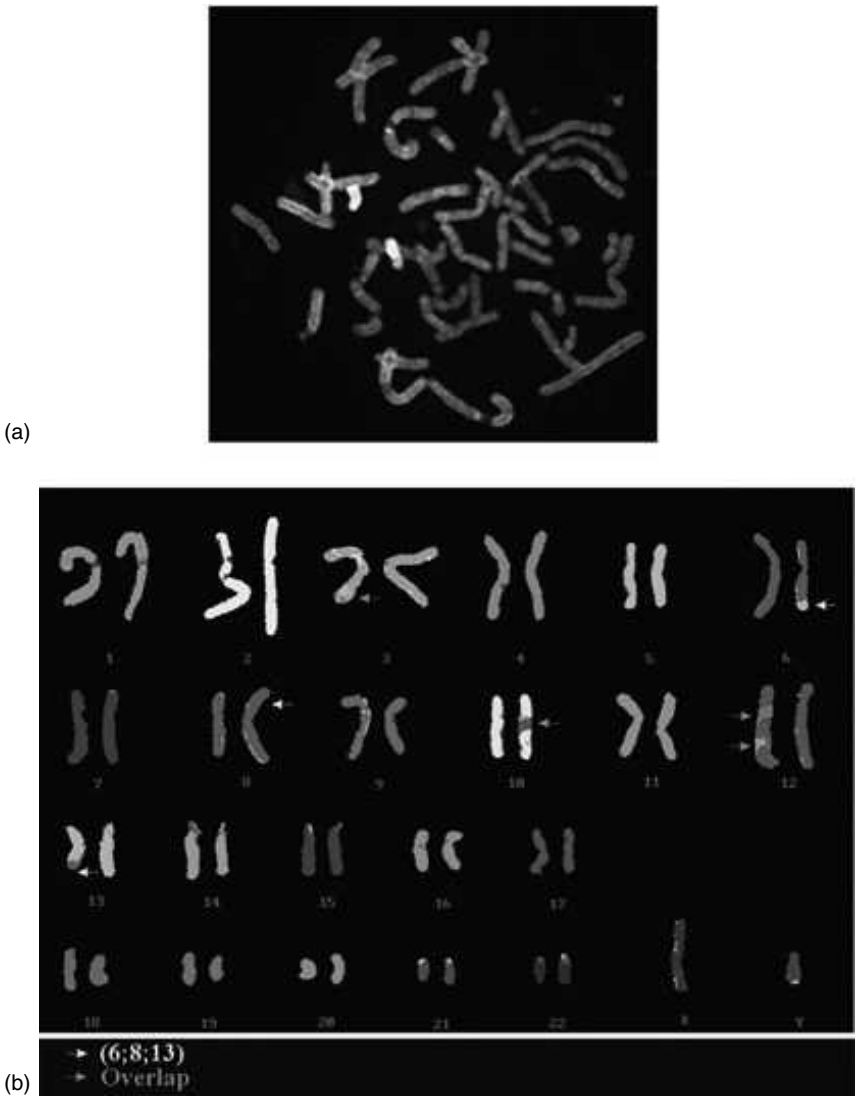

Fig. 2 Multicolor FISH. (a) Using a combination of five fluorochromes, each chromosome pair has a distinctive color. (b) This allows the identification of interchromosomal translocations between chromosomes 6, 8, and 13 in the karyotype. (See color plate p. xxii.)

color, the alternative spectral karyotyping (SKY) system analyzes the spectral characteristics of each pixel in one image using an interferometer. Both M-FISH and SKY provide similar resolution, each capable of detecting rearrangements as small as 2 Mb.

4 Chromosome Microdissection

Microdissection is an alternative method for preparing labeled chromosome-specific DNA. Glass microneedles are used under direct vision with an inverted microscope

and phase-contrast optics to scrape the chromosome of interest from air-dried chromosome preparations on a microscope slide. About 20 chromosomes are removed into a tube containing distilled water. DOP-PCR is used to make amplified primary products, which can then be used, in a further round of amplification with labeled nucleotides, to achieve the desired painting probe. The technique has been used with considerable success to generate single-chromosome-arm probes and region-specific probes. One application termed *multicolor banding* (MCB) is based on the microdissection of up to four to five regions along each chromosome. The resulting fragments are labeled with different combinations of fluorochromes so that hybridization to a metaphase produces a series of colored bands along the chromosome. This has been used to detect inversions and insertions in diagnostic cytogenetics. However, the technology is complex and is at present confined to the research laboratory.

5 Gene Mapping

Chromosome-specific DNA produced by flow sorting of chromosome suspensions can contribute to the assignment of genes to their respective chromosomes, provided that a DNA sequence from within the gene is known. In this method, PCR primers from both ends of the DNA sequence are used to amplify the gene in a panel made from primary amplification products of each chromosome, both in pools of five to six chromosomes and separately. It has been found that more than 85% of known genes can be mapped in this way. The method provides a rapid procedure for assigning linkage groups to the chromosomes of poorly mapped species, as has been shown recently in the construction of the genetic map of the dog.

Gene mapping in many species has been advanced by the construction of homology maps based on the results of reciprocal cross-species chromosome painting with chromosome-specific probes from the well-mapped human and mouse chromosomes (Fig. 3). While it is straightforward to assign linkage and radiation hybrid groups to their respective syntenic blocks in other species, their orientation and gene order has to be determined by FISH mapping on metaphase preparations with locus-specific probes (see chapter on FISH methods for the types of probe available). This is because intrachromosomal rearrangements, that is, inversions and insertions, are known to be relatively common events in species divergence. A higher level of resolution in obtaining gene order can be obtained from the longer chromosomes observed in interphase nuclei. However, the highest resolution by cytological methods is achieved using FISH on extended DNA fibers (Fig. 4). These fibers are produced by methods that release the DNA molecule from its associated proteins, especially histones, and allow spreading of the naked DNA molecules on microscope slides. Cloned DNA sequences of 1 kb or less can be hybridized successfully, and these can reveal such detail as the order and relative size of the exons and introns comprising a single gene. For further detail, DNA sequencing can be used, which is the ultimate level of resolution in gene maps.

6 Chromosome Painting in the Diagnosis of Chromosome Aberrations

Abnormal chromosomes can be sorted as well as normal ones provided they

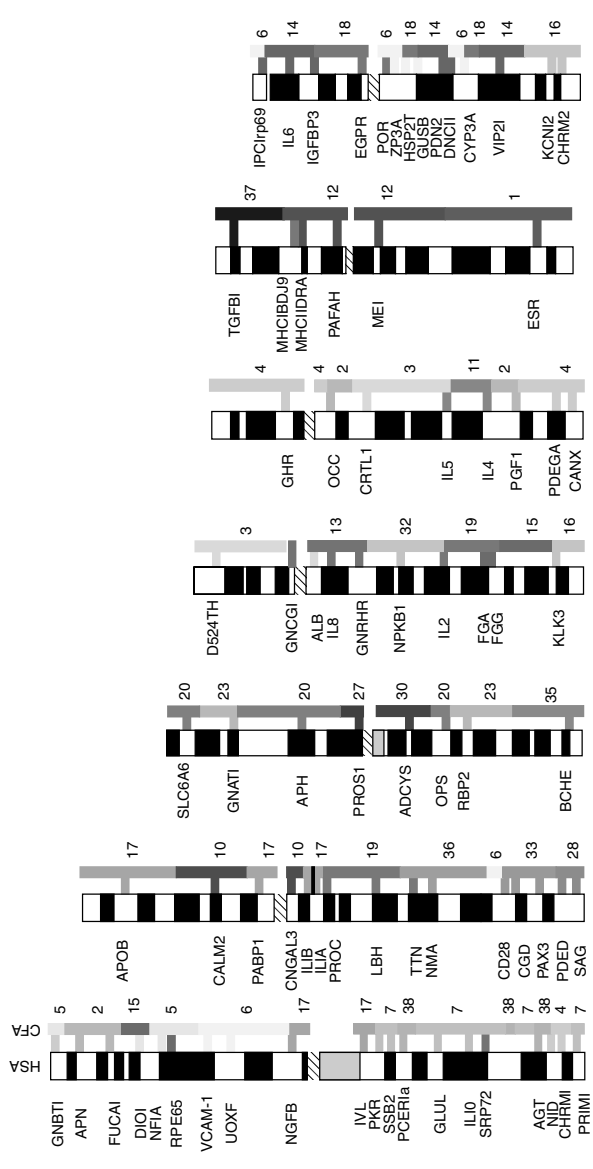

Fig. 3 Partial homology map based on reciprocal chromosome painting between domestic dog and human. The human karyotype is represented by a diagram of chromosomes 1 to 7 against which homology with segments of the dog chromosome complement are shown on the right, and selected gene markers are shown on the left.

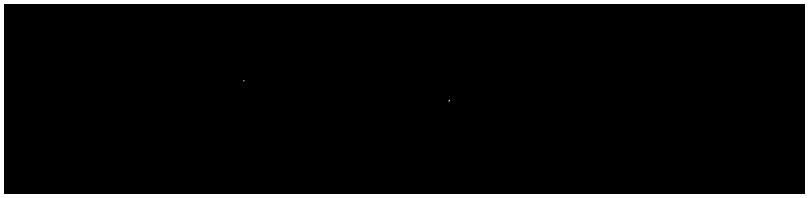

Fig. 4 DNA fiber FISH showing order of three 130-kb BAC clones from the DMTR1 locus on human chromosome 9.

are separated from others in the flow karyotype. When paints are made from such aberrations and hybridized to normal metaphases (reverse painting), their origin from normal chromosomes can be determined rather precisely. Translocations involving two or more chromosomes are evident from the number of chromosome regions highlighted by the paint probe. Intrachromosomal duplications, which are among the most frequent aberrations, are evident from the observation that only one pair of chromosomes is painted. The duplicated region may be revealed by an increased dosage of label over the duplication.

Reverse painting can also be applied to probes prepared from the microdissection of abnormal chromosomes, especially small supernumerary chromosomes. However, the more usual approach is to use M-FISH or SKY systems in the analysis of complex aberrations. Where these are not available, single whole-chromosome paints (WCP) can be used in sequential rounds of denaturation and hybridization until the nature of the aberration is revealed.

As neither SKY nor M-FISH, nor WCP methods, can resolve inversions, color-banding methods have been developed to solve this problem. The published methods include bar code approaches using differentially labeled fragments of chromosome derived from radiation hybrids of human and rodent cells, each clone containing only a small number of human chromosome fragments. Different labels are used for each clone, so that the resulting paint probe set produces a series of color bands along each chromosome. The Harlequin approach (Cambio) uses M-FISH-labeled gibbon chromosomes, which when painted onto human chromosomes produce a color-banded appearance reflecting the 80 or more interchromosomal rearrangements that have occurred during the divergence of human and gibbon species. The MCB approach achieves a banding appearance by using several fragments removed by microdissection from each chromosome and distinguishing each fragment by a different combination of fluorochromes. All these methods can be used in the analysis of intrachromosomal rearrangements in both constitutional and neoplastic cytogenetics.

One of the aims of using multicolor painting probes in human and cancer cytogenetics is to identify the genes involved at the breakpoints of rearrangements. It has been found that these breakpoints may be associated with deletion or disruption of DNA followed by loss of gene function relevant to the phenotype. The strategy is first to identify the sites of the rearrangement and then to FISH-map the region using a series of BAC or other types of cloned DNA known, from the gene map, to be within the region of interest. Once

a clone that bridges the breakpoint has been found, subclones in plasmids can be used to narrow down the area to a point when DNA sequencing can be used to identify the pathological change. A more effective approach, based on comparative genome hybridization (CGH), has recently been introduced. Flow cytometry is used to isolate and collect the two derivative chromosomes involved in a rearrangement. Each is amplified, labelled with red and green respectively, and the mixture used to probe a microarray of genomic DNA reference BAC clones. Some 3000 reference clones (unlabeled), selected because they span the entire human genome at approximately 1-Mb intervals, are arrayed on glass slides for this type of analysis. The arrays are scanned to detect the ratio of red : green in the hybridization signals generated in each clone by the probe mixture. The information is examined in relation to the genetic map. This reveals the constitution of each derivative and the breakpoints of the rearrangement. A clone that gives an intermediate red : green ratio may be one that spans the breakpoint. The technique termed *array-CGH* has particular application in the identification of cancer genes and genes involved in dysmorphic and handicapping syndromes associated with constitutional chromosome aberrations. It is likely that the reference set of 3000 BAC clones will become an important part of the cytogeneticist's armamentarium in the future, both for array-CGH and for FISH mapping.

7 Karyotype Evolution

The extensive conservation of genetic information in the animal kingdom is evident from gene mapping studies, which show that the same groups of genes are often linked together in a wide range of species. In closely related species, this conservation often extends to the pattern of G-banding revealed by conventional karyotype analysis. The X-chromosome of placental mammals is a particularly striking example of conservation as it contains virtually all the same transcribed genes in every mammalian species. In marsupials, the homology with the human X is confined to the long arm of the human X. Human X short-arm genes are autosomal in marsupials. In birds, the Z-chromosome in all species studied has close homology with human chromosome 9, and the equivalent of the human X-linked genes are to be found mostly in two autosomes, for example, in chicken chromosomes 1 and 4.

The results from comparative G-banding studies are often difficult to interpret, and it has been found that cross-species chromosome painting gives much more accurate evidence of chromosome homology between species. As indicated in the Introduction, there are two main limitations of the painting method. The first is that intrachromosomal rearrangements cannot be detected unless interspersed with chromosomal exchanges (see Fig. 3). The second is that the efficiency of cross-species hybridization diminishes as the relationship between the two species becomes more distant. In general, reciprocal chromosome painting works well between placental mammals, but is difficult between mammals and marsupials and between mammals and birds. There are exceptions, and paints prepared from the tamar wallaby X hybridize, albeit weakly, with the long arm of the human X. In addition, paints prepared from human chromosome 4 have been reported to hybridize to chicken chromosome 4

in accordance with comparative mapping data; this result illustrates a remarkable degree of genomic conservation between species estimated to have diverged over 300 million years ago.

Chromosome rearrangements that have occurred during evolution can be used to study the degree of relationship between species and to speculate on the ancestral karyotype. When the same rearrangement is found in two species from separate families, but which is absent in all other species, it can be assumed that the shared rearrangement is a recent event in evolution. On the other hand, a rearrangement that is common to a wide range of divergent species (outgroup species) can be regarded as ancestral. It can usually be assumed that when large blocks of DNA homology identified by chromosome painting are retained intact in distantly related species, this arrangement represents the ancestral condition. When these blocks are divided between different chromosomes in a single species, or in a group of closely related species, the rearrangements responsible may be regarded as recent evolutionary events. Occasionally, an ancient rearrangement may be reconstituted by a more recent event, that is, there is a reversion to the ancestral state. Much can be learned about phylogenomic relationships and karyotype evolution from these chromosome-painting studies between closely related species and outgroup species. As a result, some conclusions can be drawn about the nature of the ancestral karyotype of all placental mammals.

A recent evolutionary event is the well-known fusion of ancestral chromosomes to form human chromosome 2. All extant great apes do not show this fusion, which must have arisen in the human lineage following divergence of the chimpanzee and human lineages from their common ancestor. In another example, which relates to the evolution of the primate chromosome destined to become the short arm of human chromosome 2, the gorilla and orangutan have a pericentric inversion, which is absent in both human and chimpanzee. At first it was thought that the arrangement in human and chimpanzee had occurred subsequent to the divergence of the gorilla and orangutan and therefore served to link chimpanzee and human. It was later found that the inversion was absent in Old World monkeys (outgroup species), indicating that the human arrangement in this case is the ancestral one. The inversion in the gorilla and orangutan must have occurred subsequent to the divergence of humans and chimpanzees from the lineages, leading to the other great apes.

Chromosome painting with human probes reveals a number of ancient syntenic blocks in outgroup species that are split between different human chromosomes (Table 1). For example, the homologues of human chromosomes 14 and 15 are fused in one or two blocks in most mammalian species with the exception of the apes, dog, and giant panda. In the latter two cases, independent fission events have occurred as comparatively recent evolutionary events. Other ancient syntenies are found to characterize orders and families and, sometimes, small groups of species. Their discovery can be helpful in assigning a species to its place in the phylogenetic tree. For example, it has been shown by comparative painting with dog paints that the common ancestor of the domestic dog, red fox, Arctic fox, and raccoon dog had a small chromosome number composed of 38 autosomal segments and that a number of specific

interchromosomal rearrangements distinguish the karyotypes of each species. As the dog has a chromosome number of 78, the change from low numbers has been achieved by a series of fission events, with the formation of new centromeres. Chromosome fusion, on the other hand, has been the mechanism by which the three pairs of chromosomes of the Indian muntjac ($2n = 6, 7$) have evolved from an ancestral deer karyotype of $2n = 70$. This is illustrated by painting chromosome-specific probes of the Chinese muntjac ($2n = 46$) onto Indian muntjac chromosomes. Each Indian muntjac chromosome can be shown to be formed by the fusion of several apparently complete Chinese muntjac chromosomes (Fig. 5). Remnants of ancestral centromeres can be demonstrated at most of the fusion sites, indicating frequent centromere–telomere events, although this remains to be confirmed by molecular analysis.

Comparative studies of the genomes of mouse and human at the DNA sequence level now show that evolutionary breakpoints tend to occur within clustered gene families. It seems that the most likely mechanism is meiotic recombination between homologous sequences on nonhomologous chromosomes or chromosome segments, that is, a similar mechanism that occurs in the formation of pathological rearrangements both in somatic and in germ cells. Speciation can now be seen as resulting largely from the gain or loss of sequences within gene families, leading to the degeneration of some genes of known function and the generation of new genes of different function. It is believed that duplication events are the main source of evolutionary novelty.

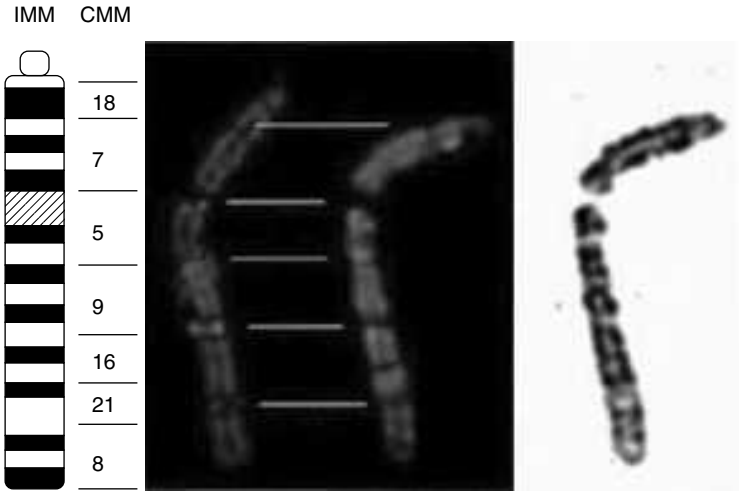

Fig. 5 Indian muntjac (IMM) chromosome 3 to which chromosome-specific paint probes of the Chinese muntjac (CMM) have been hybridized. This reveals that this chromosome has been formed by the tandem fusion of seven entire chromosomes of the Chinese muntjac. A centromere probe (red) indicates that remnants of ancestral centromeres are still present at the sites of fusion. (See color plate p. xxiii.)

8 Conclusions

The utility of chromosome painting extends from diagnostic cytogenetics to its application in comparative gene mapping and to studies of karyotype evolution. The development of highly effective techniques for sorting pure samples of chromosomes in fluid suspension has played a central role in theses advances. Future understanding of genome functions relating to gene regulation, chromosome structure and behavior, genome evolution, and the significance of noncoding conserved DNA will depend on the construction of comparative maps in a wide range of species. Only by such comparisons will it be possible to determine which parts of the genome are conserved in evolution because they retain vital functions. In these comparisons, chromosome sorting can be expected to continue to play a useful role.
